Up to a decade or two ago the works on general surgery were wonderfully deficient in the way of giving any real information concerning this important class of disease, so it was no wonder that the reader gained nothing in perusing the pages bearing on their treatment. The consequence was that the general profession was almost without literature on the subject save what could be found in a limited number of special works. Therefore, people so affected sought refuge at the hands of men outside the profession, who lured and enticed them by glaring advertisements in the daily press, or by circulars. I am sorry to add that some recent works on surgery give but little information or space to the consideration of these diseases. For instance, one of the most recent books issued on general surgery has this to say in regard to fistula in ano: "The operation for fistula in ano consists in inserting a grooved director into the external opening and pushing it through the sinus until the distal end can be felt in the rectum, then divide with a sharp knife all the tissue above the director." Now, in truth, not one in twenty cases would be cured by following these directions.

In a splendid surgical work just issued appears these words in dealing with the same affection: "Fistula in ano seldom needs operating upon as most all these cases are of tuberculous origin." What a remarkable statement. If taken as a fact, consider how many hundreds of people would go without an attempt to cure them, when they could be easily cured. Not only is the first part of the statement incorrect, but even if it were correct, in the light of modern pathology, these are the patients above all others who should receive prompt attention. Many persons have been prevented from having general tuberculosis by having a tuberculous fistula eradicated. But these cases constitute but a small percentage of this class. The fact that many medical colleges have established a Chair devoted to the teaching of this class of disease and that all post-graduate schools teach them clinically leads us to the hope that all such false doctrine will be corrected. The literature on this special branch, furnished by the members of the Association, will bear good fruit in this line.

Special works too have emanated from your pen and to-day they are used as text-books in the schools. Indeed, the student demands that his instruction in this branch shall equal that given in gynecology, diseases of the eye, ear and throat, genito-urinary, or any other branch.

Shall the treatment of these diseases constitute a specialty? Fifty letters a year is a small estimate of the number of letters that I receive saying that the writers desire to make diseases of the rectum a specialty. I confess that I am at a loss to know how to answer them. In the first place, the writers are very, very busy men, for they usually state that they have but two or three weeks to devote to the matter. Considering the many diseases which make the rectum an abiding place, all having a different pathology, and a number requiring not only careful, but skilful and dangerous surgery, I say that it would be a difficult task to elucidate the whole subject in two or three weeks, granting that I had the ability to do so.

Please permit me to say most emphatically that, in my opinion, no one should think of entering a specialty of any kind in medicine or surgery who has not been in general practice for five or ten years, preferably the latter. Again, the term specialist naturally implies authority, and certainly no one can be an authority on any subject surgical who has not given that subject long and careful study, and has had abundant opportunity to profit by clinical instruction.

The bane of specialism to-day is the "blooming out" of a class of men to practise specialties, who have no practical knowledge of the same. Such action should receive the strongest censure from the entire profession. What right have these men to claim a knowledge above their fellow practitioners? Their practices are on a level with that of the charlatan, and should be so treated. What right has such a man to endanger the lives of innocent but confiding patients—victims would be a better word—by such outrageous conduct. For the protection of women and children, at least, let all such pretenders be ignored.

I take it that the object of this assembling together is mainly to encourage the better understanding of these diseases by the reading of papers and the free discussion of the same. If you will permit me, I would suggest that the membership be made up of those who desire a better knowledge of proctological subjects, whether he be a general or special surgeon, a gynecologist or obstetrician. Indeed, it is by the diffusion of such knowledge in a general way that we are to profit. Considered from a special standpoint it might be well to try to demonstrate that it is just as difficult to excise a rectum as it is to remove an ovary; that it requires as much surgical knowledge to anastomose the colon around a stricture as it does to sew up a lacerated perineum; to do a colopexia as to remove a fibroid tumor; or to do a colostomy properly as to do a trachelorrhaphy.

In regard to the papers read before this society I would suggest that they be in strict conformity to subjects proctologic. The domain of other special societies should not be invaded by your discussions. Let members of other special associations join you, but more for the purpose of hearing these subjects elucidated by men who have given them special study. If you should desire information concerning genito-urinary, gynecological or other special departments you should attend their organizations. They will re-

turn the compliment, I am sure, by listening to you. If they expect to do rectal surgery they will profit by your deliberation; if you expect to combine genito-urinary, gynecological or other work with ours, you will profit by listening to them. A fair and equal exchange, I imagine.

In a word, I take it that this society is not to be composed of men who limit themselves to the practice of rectal diseases only, but to a membership desiring to become better posted in the treatment of this class of disease. Whether a man shall limit his practice, and how, is his own concern, but this body has a far more definite object to attain. Let us do this with a spirit of great friendliness for our neighbor specialists, feeling that it is the relief of suffering humanity that we desire, and not personal aggrandizement.

Taking this as your first real meeting, permit me to congratulate you upon this auspicious beginning. Let your standard be a high one, and in this connection I beg to make the suggestion that you should consider the propriety of annexing this Society as a Section of the American Medical Association. Members of this great body are anxious always to hear papers and discussions on all subjects when in attendance on that body. Surely yours would be a great acquisition to the mother society, and many who attend it are interested in this special branch.

I would warn you concerning application for membership. Your rules should be the more rigid for the reason that many unethical men have in the past been engaged in this special work. Then, too, a specialty oftentimes becomes a "fad" and the temptation to overstep the bounds of decency inviting. I would call your attention to Article I., Section III., in the code of ethics of the American Medical Association, and a rigid adherence to the same should be demanded of all applicants for membership in this body:

"It is derogatory to the dignity of the profession to resort to public advertisement or private cards or hand-bills inviting the attention of individuals affected with particular disease, publicly offering advice and medicine to the poor, gratis, or promising radical cures; or to publish cases or operations in the daily prints, or suffer such publications to be made; to invite laymen to be present at operations, to boast of cures and remedies, to adduce certificates of skill and success, or to perform any other similar acts. These are the ordinary practices of empirics and are highly reprehensible in the regular physician."

I see before me men rich in fame and to whom the profession is indebted for valuable research. New instruments, new operations, scientific and original investigations, learned articles, are accredited to you. Let this Association be an inspiration that will keep your zeal aways keen, and your energy undiminished.

After twenty years or more of work along this special line I now see and feel a glad fruition of my hopes, and I am encouraged as I have never been before. I realize too that a few more years will let me "out of the harness," but my consolation is that I will leave the work which has so interested me in abler hands than mine, and that in a humble way I have aided some in the relief of suffering humanity. God speed you, Gentlemen.

MEDICAL PROGRESS.

Bichloride Baths in Variola.—Thirty-six cases of variola, of which one was hemorrhagic and thirteen confluent, were treated by H. A. Ingalls (*Jour. Am. Med. Assoc.*, April 28, 1900) by means of bichloride baths. The baths were given with the idea of lessening the stage of pustulation and the consequent pitting, in the belief that the ordinary pus cocci in the pores of the skin caused the pustulation. The resulting diminution of the pustulation and pitting, of the disagreeable and peculiar odor of the disease, and of the distortion of the features at the beginning of the disease, and the fact that the patient was rendered more comfortable, without any opium, were so encouraging in the first case in which the baths were tried that they were used in all the succeeding cases. The baths were given in the following manner: A bathtub placed at the side of the patient's bed was filled with a solution of bichloride—1 to 10,000—at a temperature of from 103° to 105° F. The patient was then placed in the tub, his head and shoulders being kept above the solution, and the whole body was gently rubbed with a soft cloth. The patient remained in the bath for about ten or twelve minutes, and was then carefully dried, put in clean clothing and placed in a clean bed. These baths were given night and morning. Immediately after the bath the patients felt more comfortable, but in a little while there was a burning sensation "just beneath the skin." For this disagreeable sensation the writer anointed the patients immediately after the bath with a mixture of carbolic acid, bismuth subnitrate and olive oil, which did away with this uncomfortable symptom. The writer thinks that this bichloride-bath treatment is the best yet presented, and cites in detail four of his thirty-six cases. From his observations in these cases he comes to the following conclusions in regard to this treatment: (1) There is practically no mortality. (2) The suppurative fever can be shortened four to six days if the patient is treated from the onset. (3) A minimum of pitting is secured and an almost entire absence of the characteristic, disagreeable odor. (4) The period of desquamation is materially lessened, owing to the thinness of the scab formation. (5) Pain is much reduced, morphine being rarely indicated. (6) The great distortion of features, which gives us such repulsive looking patients, is eliminated to a great extent.

An Early Sign of Tuberculosis.—T. F. Harrington (*Jour. Am. Med. Assoc.*, April 28, 1900) calls attention to the occurrence of a widely dilated state of both pupils as an early sign of tuberculosis. This dilated state is not a paralysis of

the pupils, but rather a condition in which the pupils are in a more or less constant state of dilation, due to some irritation along the track of the nerve-fibers in the ciliospinal region; or perhaps an irritation of the sympathetic, brought about by some blood-change associated with very early tubercular infection not yet fully recognized. The writer has often noticed this condition of the pupils in persons apparently well, and also in others in whom there was no reason for suspecting tuberculosis; and so frequently has tuberculosis followed at a later day in these same persons that he has come to associate widely dilated pupils with incipient tuberculosis. The writer admits that, while he has observed this sign very frequently in cases which afterward developed tuberculosis, it is not infallible, and it may occur in some persons in whom tuberculosis never develops, and again it may never appear in persons who do develop tuberculosis. While the value of this premonitory sign has yet to be confirmed, the writer has become more guarded in giving a prognosis in those cases in which such dilation of the pupils is present.

Diagnosis of Pernicious Anemia.—A. Abrams (*Med. Rec.*, April 28, 1900) reports two cases in which the diagnosis was difficult by clinical signs on account of the prominence of stomach signs. In both cases there was a marked progressive anemia and emaciation with gastric irritability. In one case vomiting was almost a daily occurrence and an examination of the vomitus invariably demonstrated the absence of hydrochloric acid and the presence of lactic acid. In the other, test-meals gave the same results. There was considerable tenderness and resistance in the epigastric region and in one patient a ventricular dilatation was made out. An examination, however, of the blood made the diagnosis of pernicious anemia certain, both normoblasts and megaloblasts being present. The leucocytes were reduced from one-third to one-half the normal number, and the author believes this to be an important sign. He quotes Cabot as saying that "malignant disease may bring down the blood-count to 1,000,000 or lower, but in such cases leucocytosis is always present." Both of these cases were treated with Fowler's solution and bone-marrow, but the latter was discontinued on account of its irritant effect on the stomach. Fowler's solution was increased to twenty minims three times per day and both patients improved markedly. When arsenic cannot be given by the stomach it may be administered subcutaneously or even by the rectum. Iron is useless and liable to create digestive disturbances. Relapses are best prevented by minute attention to dietetic and hygienic details.

Antitoxin in Diphtheria.—J. E. Herman (*N. Y. Med. Jour.*, April 28, 1900) defends one of his recent articles on the uselessness of antitoxin which was severely criticised in the *International Medical Magazine* by Dr. A. Robin. He brings forward further proof to show that the apparent decrease in death-rate since the use of antitoxin is largely due to the fact that the epidemic has recently been of a milder nature and that many more cases are treated for diphtheria than formerly, a goodly proportion of them being, no doubt, non-diphtheritic. He further maintains that the Klebs-Loeffler bacillus has no etiological relation to diphtheria and that it is frequently found in normal throats. He quotes Winters of the Willard Parker Hospital as saying, "Thus far I have no reason to feel that antitoxin is of any service in diphtheria in this hospital."

Hydrochloric Acid and Indicanuria.—A report of the examination of one hundred and sixty-four cases appears in the *New York Medical Journal* (April 28, 1900) by A. A. Jones, who has been led to believe by his investigations that the presence of free hydrochloric acid in the stomach does not bear such a definite relation to the presence of indican in the urine as has been supposed. He examined eighty-five cases showing free acid and no indican, thirty-six cases showing free acid and indican present in the urine, twenty-five cases showing no free acid and no indican, and sixteen cases showing no free acid with indican present in the urine. It now seems settled that indican is a product of putrefaction of albuminous matter, especially in the small intestine, caused by bacterial action, but it is doubtful how much influence the free hydrochloric acid of the stomach has. Wendt, after observing Schlatter's case of complete extirpation of the stomach, concludes that the chemical functions of the human stomach may be completely and satisfactorily performed by the other divisions of the alimentary canal and that the free acid of normal gastric juice has no power to arrest putrefactive changes in the intestinal tract. Its antiseptic and bactericide properties have been overestimated. It would appear that as long as sufficient acid *is* secreted to satisfy the nitrogenous elements, and the total acidity of contents is not much diminished, putrefaction is not liable to arise, despite the fact that free acid is not present. The bile, the pancreatic secretion and the *succus-entericus* all have, no doubt, an antiseptic action and the epithelial lining may possess an inhibiting power. In other words, if the albuminous elements undergo digestion they do not putrefy, and in many cases indicanuria is an index to the adequacy of intestinal digestion without regard to the state of the stomach.

Diagnosis of Hysteria.—According to C. W. Burr (*N. Y. Med. Jour.*, April 28, 1900) the best definition of this condition seems to be that of Möbius, "A state in which ideas control the body and produce morbid changes in its functions." The diagnosis is made by discovering symptoms peculiar to it and by exclusion—by proving the absence of any other condition. The mode of onset and the grouping of symptoms is important. Violent contractions may come on suddenly after a fit or follow some emotional excitement. This never occurs in organic paraplegia.

The grouping is often characteristic, sometimes only one symptom being present, as aphonia, the fit, a palsy or an hysterical joint. A symptom group such as hemiplegia, hemianopsia, and aphasia, which can be explained by locating the lesion in a particular joint, does not occur in hysteria. One may have monoplegia, and geometrical anesthesia, in which nerve boundaries and spinal levels are entirely disregarded, and segments or areas of a peculiar shape are involved. Its boundaries may shift from day to day, and it also differs from organic anesthesia in sometimes being unknown to the patient. An hysteric who is totally unable to tell when she is touched or pricked may be able to write or use the hand in any way when blindfolded. There is no satisfactory explanation of this peculiar condition. The exciting cause is also important. Some emotional or mental shock is almost always the direct agent—a cross, an accident, a disappointment, or worry. The anesthesia may be total, in which case there is insensibility to all forms of stimuli, or it may be partial, the order of the latter being analgesia, thermo-anesthesia, electro-anesthesia, and loss of all sensibility except to heat and to cold. Hyperesthesia over large or small areas is also common. They may appear anywhere, but most frequently over the ovaries, along the spine, on the breasts, just below the ribs, and at the vertex of the skull. One of the most interesting hyperalgesias mimics inflammation of joints, the hip and knee being most prone to be affected. There is never deformity of joint, shortening of bone, or evidence of pus. The diagnosis of the fit may not be easy, for the symptoms are not always clear cut, and may resemble those of epilepsy or the two conditions may be combined. Usually after some mental worry or excitement the body becomes rigid for a few moments, then a violent general chronic convulsion follows, the movements seeming almost willed and conscious. The tongue is rarely bitten, the sphincters are not relaxed. There is no asphyxiation as in epilepsy. Coma is never present but consciousness is always disturbed. In epilepsy defecation or micturition often occurs during the attack. In hysteria large quantities of pale limpid urine are passed after the attack. The paralysis of hysteria can usually be easily differentiated. It may be either spastic or flaccid. Great local wasting never occurs, and the reaction of degeneration is always absent. True palsy of the bladder never occurs, but there may be retention and obstinate constipation. The knee-jerk is usually exaggerated. One type of flaccid palsy peculiar to hysteria is that the patient may be able to keep the completely paralyzed part in any position in which it is passively put.

Cancer of Stomach in the Young.—Cancer appearing in cases under twenty years of age are clinical and pathological curiosities, but those which occur between twenty and thirty, although not at all common and may be considered as present in the young, yet they form a rather constant percentage, ranging from two to four per cent. W. Osler and F. McCrae (*N. Y. Med. Jour.*, April 21, 1900) have reviewed the cases which have been reported under twenty years of age, there being six below ten years and only thirteen cases between ten and twenty years of age. In a series of 150 consecutive cases of carcinoma of the stomach occurring in Johns Hopkins Hospital, six of the patients were under thirty years of age and these are reported in detail. Two features stand out prominently, a striking abruptness of onset, and the acuteness of the course. All cases were in males. Loss of appetite was not present in three of the six. Only one was free from pain and vomiting was present in five of the cases as was also a definite tumor. Mathieu, in his series of nineteen, estimates a mean duration of three months. In the reported series of six the duration was known in four, two being six months and two being four months. One other was probably equally rapid, while the sixth gave a history of eighteen months.

The Riding Fragment.—C. H. Golding-Bird (*Brit. Med. Jour.*, April 21, 1900) says that in fracture of the leg with riding fragment, the obstacle to reduction is not so much blood-clot, soft tissues, etc., between the tibial fragments, as it is the spring action of the fibular fragments which are driven into the surrounding fibrous tissues. Attempts to reduce the tibial deformity increase the spring of the fibular, this being more especially true in cases of spiral tibial fracture. When proper manipulation fails to keep such a fracture in good position, when the fracture threatens to become compound, when there is shortening, operation should be performed not only on the tibial fracture but also on the fibula to prevent its spring action, and the fragments fixed according to the preference of the surgeon.

Bottini's Operation.—W. Meyer (*Med Record*, April 28, 1900) says that Bottini's operation for the cure of hypertrophied prostate has come to stay. What remains to be done is to find its proper place among radical procedures and to determine its proper indications. The operation is performed under local anesthesia. Three cuts are made, a median, which is the most important, and a lateral one on each side. These cuts are made slowly with a white-hot blade. Preliminary cystoscopy is of very great assistance but must be dispensed with in old prostatics with chronic sepsis. The advantages of Bottini's operation are restoration of vesical drainage, disappearance of vesical spasms, improvement in general condition, cure of the generally present constipation; it shows the greatest percentage of cures with the lowest mortality. This operation should be done as soon as it becomes necessary to put the catheter into the hands of the patient himself, since the danger to life begins at this time. The presence of pyelitis is not an absolute contraindication to the operation, although it adds to its gravity.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS.

THE Fifth Triennial Session of the Congress of American Physicians and Surgeons, held on Tuesday, Wednesday and Thursday of this week, was most successful. The attendance surpassed that of any previous meeting. Of the scientific importance of the session our readers may judge from the very full accounts of the sessions of the first two days which appear in our present issue.

This triennial assemblage of the representative specialists of the country has become an important event in the medical world, and the last session for the Nineteenth Century marks the culmination of professional interest and the acme of dignified scientific influence.

The discussion on "Bacteriology in Health and Disease," at the first general session, drew out a representative audience. Unfortunately as specialism has become more and more emphasized the possibility of mutual influence has minimized. Special headquarters, special sessions, special dinners, have become the order of the day. Under these circumstances the idea of a number of short papers from leading men in their own lines at the general session, each on some living issue, is eminently a good one. When it is carried out, as on this occasion, by the selection of prominent authorities on what may be called the theoretic subjects, each on a theme that touches practical present-day medicine at an important point, a long step in the right direction, that of reversion to mutual influence, has certainly been taken. The interest of the second day's general session threatened to be marred by the unavoidable absence of Professor Osler. Dr. Weir Mitchell's poem, however, proved amply able to supply any and all deficiencies in the day's program. Those who had the pleasure of listening to its rendition by the doctor-poet himself will ever bear the memory of a rare privilege accorded in the midst of busy days, all the more memorable for the enthusiasm it aroused for a glorious, world-old profession.

Among the papers that attracted most attention were Dr. Trudeau's on "Sanitaria for the Tuberculosis," which we shall have the privilege of presenting to our readers in full; Dr. Thayer's on the "Etiology of Malaria;' Dr. Flexner's on the "Bacteriology of Dysentery," presenting the conclusions of his researches in the Philippines, and Dr. Clarence Blake's on the "Sociological Status of the Physician," a masterly essay on a most fruitful and interesting theme. Among the discussions of special interest was that on pernicious anemia before the Association of American Physicians. There seems no doubt that this disease is much more frequent in this country than is usually thought. Cases of the disease masquerade to death under the name of general tuberculosis, or sometimes as a typical persistent typhoid fever, or even as jaundice and hypertrophic biliary cirrhosis. The assurance of its greater frequency is accompanied by greater skepticism than ever in the therapeutics of the disease.

On the whole, this meeting of the Congress has been well worthy the closing year of an especially glorious medical century.

THE UNITED STATES PHARMACOPŒIA.

ALMOST one hundred years ago the first steps were taken for the preparation of a general Pharmacopœia and in 1808, through the labors of Dr. Lyman Spalding, of New York, there was issued the first National standard. For one hundred years the Committee of Revision of the United States Pharmacopœia have worked stead-

ily and well and the recent meeting of the Convention, beginning May 2d, was one of unusual promise. The meeting was very large, the different bodies entitled to participate were well represented.

The high level of scientific work of this body during the past was ably set forth in the excellent address of the President, Dr. H. C. Wood, and the outlines of the mold in which the Pharmacopœia of the future should be cast were sketched in broad and telling phrases. Speaking of the relationship of this book to the medical body, it was said that there was a widespread feeling that the medical profession does not properly appreciate and support the U. S. Pharmacopœia. This feeling Dr. Wood believed had some foundation, but it certainly is exaggerated. "It is true that—owing to the activity of manufacturing pharmacists and the number and skill of their commercial salesmen, aided by the deficiencies of medical education and the peculiar child-like credulity which is so common in doctors—all kinds of proprietary mixtures and proprietary articles, and extra-pharmacopœial remedies are largely used in the United States. It is so easy for the lazy doctor to write for Smith's Panacea for Human Ills, and so easy for the doctor who knows neither Materia Medica nor Therapeutics to order Jones' Consumption Cure, or Thomas' Kamiantia, that so long as laziness and incompetence remain with us, so long will this thing be done. But this is no fault of the Pharmacopœia, and no perfection of the Pharmacopœia will greatly influence it."

We should feel proud of the Committee of Revision, which, under the masterly guidance of Dr. Charles Rice of New York, has given the profession such a guide, but, as pointed out in the address already quoted, there certainly seems to be a misconception as to the office and function of this book. It is not a guide to Practice, it would then have to be a Materia Medica or a book on Therapeutics. It is the apothecaries' *vade mecum*, and as such is intended primarily for them.

It is certainly the work of the trained pharmacist to give to the healer of bodily ills the best formulæ, the best simples and accurately prepared drugs. The Pharmacopœia should tell him how to make them and in that the physician has but a collateral interest, although it should be a real one; while the student of therapeutics takes that which he knows to be standard and applies such in the treatment of disease.

We shall present to our readers the able address of Dr. Wood in a shortly forthcoming issue of the Medical News.

SUNLIGHT AND HOME HYGIENE.

Although for centuries it had been more than suspected that sunlight was Nature's great disinfectant, it is only within recent years that bacteriologic investigations have shown that white light is a most powerful inhibitory agent for the growth of all forms of microscopic life. Somehow the actinic rays of white light, the same that cause the changes in the silver salts in photography, are able to initiate alterations in the chemical constituents of microbes that eventually lead to their complete destruction. Unfortunately, Nature's pervasive germicide is not allowed to penetrate into the living-room of city folk in sufficient amounts to permit the full exercise of these beneficial powers. This is true not alone in the houses of the poor, for even from the dwellings of the better class sunlight is excluded as zealously almost as if it were an instrument of harm.

The dim cathedral light that seems to many housewives the great desideratum for living-rooms is a serious preventer of important natural, hygienic processes—processes that deserve to be encouraged not obstructed. Curtains that keep out the sunlight lest it should fade the carpets or the wall-paper, or show too clearly that the housewife herself is not longer in the bloom of youth, do much more than merely darken the room. They make it a favorable living and breeding place for any bacteria that may be introduced. Hallways into which so many bacteria are brought direct from the dusty streets, instead of being the most lightsome parts of the house, are usually the darkest. Double doors and stained glass effectually preclude active sunlight.

This is not as it should be. The matter is so important that family physicians should throw the weight of their influence in favor of the greatest possible amount of sunlight in the home. For delicate children it means frequently the difference between a life free from illness and one in which delicacy of constitution becomes inveterate from recurring ailments. The improvement in health among the poor of our large cities as the result of letting in the light into the tenements shows how much good the great solar scavenger can accomplish even under unfavorable circumstances. A time will come, doubtless, when the family physician will form one of

the family council as to hygienic arrangements of the home. Meantime, the lesson must be insisted on that sunlight cannot with impunity be denied fee entrance to the house. The orange and red stained-glass windows may give elusively brilliant color effects on hangings, rugs, and furnishings, but they disarm sunlight for its conflict with disease. They shut out the precious rays at the blue end of the spectrum, odorless, noiseless, but efficient scavengers, that do Nature's work and so make life possible for the higher organisms in spite of the multitudinous germs that exist and multiply so rapidly all around them.

ECHOES AND NEWS.

The Barren Island Plant.—Governor Roosevelt has signed the bill compelling the removal of the garbage works from Barren Island, N. Y., and the abatement of the nuisance.

Contagious Diseases.—There were reported in New York during the week ending April 28, 1900: Measles, 714 cases and 27 deaths; diphtheria, 224 cases and 43 deaths; laryngeal diphtheria (croup), 10 cases and 4 deaths; scarlet fever, 105 cases and 13 deaths; smallpox, 2 cases; tuberculosis, 202 cases and 204 deaths; typhoid fever, 10 cases and 8 deaths; cerebrospinal meningitis, 3 deaths; totals, 1327 cases and 302 deaths.

The Jacobi Dinner.—The post-prandial program of the Jacobi dinner has been arranged as follows: (1) Opening address by the presiding officer, J. D. Bryant, M.D. (2) Dr. Jacobi—the Physician, by W. H. Thomson, M.D. (3) Dr. Jacobi—the Scientist, by William Osler, M.D. (4) Dr. Jacobi in Relation to Medical Education, by Hon. Seth Low. (5) (Title to be announced.) Hon. Carl Schurz. (6) Presentation of the Festschrift, by A. G. Gerster, M.D.

The Tuberculosis Congress.—The International Tuberculosis Congress was opened at the San Carlo Theater, Naples, Italy, April 25th, in the presence of the King and Queen of Italy and the Minister of Public Instruction, Dr. Baccelli. The latter delivered the inauguration speech. United States Embassador Draper was in attendance.

Morphine Prices Lower.—The price of morphine was reduced ten cents an ounce on April 23rd. This makes the third reduction during April and lowers the price from $1.90 to $1.80. The reason for this latest decline is probably the keen competition between the old and new manufacturers.

Women at Columbia Laboratories.—At a recent meeting of the Faculty of Pure Science at Columbia University it was decided to allow women who had a baccalaureate degree in a recognized college, and were candidates for higher degrees at Columbia, to use the laboratories and other facilities of working in astronomy, botany, geology and physics. This places women pursuing graduates' courses on precisely the same terms as men.

Number of Blind Increasing.—There are 705 applications for a share in the $30,000 which is to be distributed to New York City's blind this year, and as each beneficiary is to receive $50, it is feared the money may not go around, even after the investigators have thrown out the non-resident and fraudulent applications.

Radical Changes in State Hospitals.—Four physicians who have long been identified with the care of the State's insane patients in Greater New York are summarily legislated out of office by the Burnett bill, which has now become a law, having been signed by the Governor. These men are Dr. A. E. Macdonald, General Superintendent of the State Hospital at Ward's Island; Dr. Oliver M. Dewing, General Superintendent of the State institution at King's Park; Dr. Elliot, Medical Superintendent of the old hospital at Flatbush, and Dr. Herman C. Evarts, Medical Superintendent at King's Park. It is understood at the office of the State Commission in Lunacy that for the present, however, until other arrangements can be made, the present superintendents will be permitted to retain their positions, as it is desired that the change shall in no way impair, even temporarily, the efficiency of the institutions concerned.

Philadelphia Health Report.—Returns of deaths for the week ending April 28th, show a large decrease. The total number was 618, a decrease of 121 from those of last week and an increase of 117 over the corresponding week of last year. Contagious diseases: Diphtheria, 70 cases, 21 deaths; scarlet fever, 68 cases, 6 deaths; typhoid fever, 74 cases, 18 deaths.

Maurice Porter Institution for Children.—By the increase of the staff of this Chicago institution, the facilities for the training of nurses will be improved. A two-years course of training will be given. Children are admitted only between the ages of two and twelve. This hospital was incorporated in 1894. The staff now comprises the following well-known physicians and surgeons: Drs. N. Senn, Frank Billings, Truman W. Miller, Norman Kerr, M. L. Harris, J. W. Oswald, W. S. Christopher, W. W. Quinlan, W. D. Stores, J. B. Houston, Samuel J. Walker, George F. Fiske, A. M. Hall, R. R. Campbell, M. Herzog, Hugh T. Patrick, and George Chapman.

Exhibit of Public Baths.—An exhibit of the free public cleansing baths of America will be made at the Paris exposition, under the auspices of Dr. Simon Baruch of New York. For the introduction of the public rain-bath into this country the people are indebted to Dr. Baruch; indeed, he is the originator of the plan and has

succeeded in having them introduced in several cities of the United States. Chicago has three, Buffalo one, and New York one in process of construction. These are the only baths of this kind in the world.

Smallpox in Chicago.—It should be noted that every case of smallpox in Chicago during the last fifteen months, both the imported cases and those contracted by residents from the imported cases, has without exception been unvaccinated. There has been no case among the vaccinated. The verdict of the medical profession at the end of a century of vaccination is that, with the exception of a very small number of insusceptible individuals, every unvaccinated person would contract smallpox in the course of a natural lifetime, if exposed to the contagion, and fully one-half of those attacked would die, while of the survivors a large number would be hideously disfigured, maimed and disabled. On the other hand, if efficiently vaccinated and revaccinated, an equally infinitesimal number of hypersusceptible individuals would contract the disease on exposure, and of this small number less than one in a hundred would die. One-tenth of the human race, on the average, died annually of this disease for centuries before the discovery of vaccination, during which period, in the forcible language of Lord Macaulay, "The disease was always present, filling the churchyards with corpses, leaving on those whose lives it spared the hideous traces of its power, turning the babe into a changeling at which the mother shuddered, and making the eyes and cheeks of the betrothed maiden objects of horror to her lover."

Sanitation in Chicago.—Health Commissioner Reynolds recently addressed the Chicago Academy of Sciences at its meeting on some problems of sanitation in Chicago, and among other things he said that the sanitary problems of this city differ from those of most cities with regard to the drainage and water supply, and the fact that the loose, friable soil, on which the city is built, naturally produces dust or mud, according to the weather. The immense quantities of bituminous coal that are consumed continually adds to the impurities of the surface and the atmosphere. The solution of the drainage and water problems will be accomplished when the sanitary waterway and its auxiliary, the intercepting sewer, are completed. As sunlight is the great life-giving principle for man and the chief enemy of diseases of germ origin, greater care in the future will be taken in the construction of residences, shops and offices, so that an abundance of light will have free access to every part of the building. There is much hope for a better sanitary condition in the fact that the people are becoming better educated in the nature and prevention of disease. If the present percentage of increase in the duration of life in Chicago is kept up, the city soon will become famous as a great health resort. The bulletin of the Department of Health for April, 1899, shows that during a generation the duration of life in this city has more than doubled. Thirty years ago the average age for deaths in Chicago was 13.9 years. At the present time it is 29.4 years. With an average annual death-rate of 14.4 per thousand during the years 1894-98, compared with an average annual rate of 40.6 per thousand from 1845 to 1854, a saving of 42,050 lives per annum can be demonstrated.

Medical Missionary Work.—Medical and educational work and their connection with missions were the topics discussed at the meeting in New York on April 30th of the delegates for the Ecumenical Conference on Foreign Missions. Many of the missionaries assembled were physicians as well as teachers, and in their addresses it was made clear that a missionary, to be successful in a foreign field, must devote almost as much time to the physical as to the spiritual welfare of the people among whom he goes. As a rule, the missionaries have to content themselves with a very limited stock of medicines and few instruments, but every missionary, it seems, should have some medical and surgical training and must always be ready to undertake the cure of any disease brought to his attention.

Confidences of Physicians.—The New Haven Medical Society is aroused against a recent ruling in a case before the Superior Court in New Haven and has taken preliminary steps looking to the repeal of the law that enables a judge to compel a physician to testify to what the physician regards as privileged communications between himself and his patient. As the Connecticut law now stands, such communications are not deemed privileged and must be divulged in court as testimony. The New Haven Medical Society considers that the rule of common law should be overruled by the enactment of a statute similar to that in New York and seventen other States.

Vote against Women Nurses in Army Hospitals.—On April 24th the Senate Committee on Military Affairs, by a vote of 6 to 5, ordered an adverse report on the bill providing for the employment of women nurses in military hospitals of the Army.

Only Men Nurses for the "Maine."—It was decided in London on April 26th that the hospital ship "Maine" shall return to South Africa. Hereafter she will carry no women nurses, all the nursing being done by men trained in the American Ambulance School.

Pathology in the University of California.—Mrs. Phœbe A. Hearst has presented to the University of California a complete equipment for the department of pathology, which will make this department equal to, if not greater than, that of any university in America.

Aphasia Patient at Harlem Hospital.—Gero Martino, an Italian, was shot in the head on April 10th, and taken in an unconscious condi-

tion to Harlem Hospital. A portion of brain tissue was removed. It was thought that he would die; nevertheless he is now convalescent. Martino has lost the use of his tongue and cannot remember things. He will probably never regain these faculties.

Smallpox in Winnipeg.—A very malignant type of smallpox is epidemic in Winnipeg, Manitoba. Eighteen cases were reported on April 27th, many of whom were not expected to survive. Health Officer Inglis believes that Winnipeg is threatened with the worst epidemic in Canada since that of Montreal in 1885.

Tuberculosis Congress Adjourns.—The International Tuberculosis Congress at Naples concluded its sittings on April 28th. An international committee will be organized by Dr. Lannelongue of France, the Duke of Ratibor of Germany and Professor Bacelli of Italy. These gentlemen will appoint an equal number of members to represent each of the the three countries.

SOCIETY PROCEEDINGS.

CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS.

Fifth Triennial Session, Held at Washington, D. C., May 1, 2, and 3, 1900.

[Specially reported for the Medical News.]

GENERAL SESSION.

FIRST DAY—MAY 1ST.

Adaptation of Pathogenic Bacteria to Different Species of Animals.—Dr. Theobold Smith of Boston pointed out that medical science and medical art have to do chiefly with the phenomena of human disease. That which medical science wants to know is the series of causes or antecedents leading to any given disease and the series of phenomena which unfolds itself within the body during disease. Medical art desires to know where human ingenuity may come to modify, suppress, or eliminate portions of this series, so as to interfere with the progress of the disease and bring it to a standstill. Hygiene, by common consent, devotes itself to the external phenomena; pathology, to the internal. A small proportion of the infectious diseases of man and a large proportion of the infectious diseases of higher animals are transmissible, or at least, inoculable upon smaller animals producing in them diseases which have more or less constant characters. The range of infectiousness varies considerably and arbitrarily without any at present assignable reasons. The range of infective power seems to a certain extent to coincide with the readiness with which the bacteria can be artificially cultivated on various substrata. Or, in other words, with their degree of saprophytism. Thus, the plague bacillus, the colon derivatives, the rabbit septicemia group, and anthrax, are quite readily cultivated and their range is very wide. Investigation of infectious diseases of animal life has brought before us another phenomenon which is of considerable importance. Certain bacteria causing disease among different species have certain affinities which cause us to classify them together and which enable us, at the same time, to clearly separate them from other pathogenic groups. One of the most important of these groups consists of derivatives of the colon bacillus which produce epizootics among swine, guinea-pigs, field-mice and spermophiles which have been found associated with disease in horses, cattle and certain birds.

Outbreaks of meat-poisoning in European countries characterized by gastro-intestinal disturbance are most likely due to some forms of the paracolon bacilli and paratyphoid bacilli. The typhoid bacillus is probably a more highly modified offshoot of this same stock. There is much minor variation among these derivatives, which is probably due to an adaptation to different animal hosts. We might say that the colon bacillus or some ancestral form possessed certain qualities favorable to parasitism which have enabled it to become a prominent pathogenic power under the form of a number of varieties. The tubercle bacillus furnishes us still another illustration. The avian type has been recognized as a variety for some years. Similarly, the tubercle bacillus of cattle has certain uniform characters which have thus far been found from culture in the human subject. There is one other question which is more or less associated with the subject, the fluctuation of the virulence of pathogenic organisms and the bearing of this upon the appearance of infectious diseases in epidemic form. The commonly accepted view of the gradual self-limitation of epidemic diseases is the exhaustion of susceptible material. The recrudescence is similarly ascribed to the reappearance of a young, susceptible generation. Thus, the reappearance of the Eastern plague after an interim of months is ascribed by one observer to the new generation of rats. If we indulge in a little speculation along teleological lines we shall see that the attenuation of virus limited to one host is not an unreasonable hypothesis. We may assume that all parasitism tends toward a more or less harmless symbiosis.

The author said that he believed the great specific energy of many disease germs was acquired in early geologic ages, possibly in animals of a very different type from those now living. But it is not improbable that the process of making bacteria is going on now in the animal world, if we notice only that these bacteria have been transported by some accident from their unseen habitat to species which happen to be susceptible.

A Study of the Mechanism of Agglutination.—Professor Harold C. Ernst of Boston held that in the early observations on the agglutinating properties of the serum of immune animals the facts in the cases were developed with motile bacteria

as with Charrin and Rogers' (1899) studies with bacillus pyocyaneus in cultures in the serum of immune animals and Pfeiffer's reaction in cholera, typhoid, etc., and it is notably the case now that the most definite reactions are obtained usually with motile bacteria. After reviewing the contributions to medical literature Dr. Ernst said that the relation between the agglutinating property and the bactericidal property is equally indefinite from the point of view of immunity. The rat, with an extremely bactericidal serum does not agglutinate at all. In the dog, also with a bactericidal serum, agglutination occurs very remarkably. Nor are the origin or chemical properties the same. The studies already made seem to show that the agglutinating property does not lie in, and is in no way connected with, the flagella of the bacteria concerned; that agglutination is not to be accepted as a specific property connected with a condition of immunity, although this is a difficult idea to give up; that a homologous nature of agglutination cannot be considered a positive characteristic, for how, then, explain the clumping of typhoid bacilli by diphtheria antitoxin. Finally, that no universally applicable explanation of agglutination has yet been offered.

Relation of Bacteriology to Clinical Medicine.—Dr. Richard C. Cabot of Boston was of the opinion that bacteriology is in closest relation with clinical medicine by the help it gives in clinical diagnosis. Such assistance is given through the demonstration of the bacilli themselves in secretions or in the products of disease; through the agglutination tests; through the injects of soluble products of the growth of certain bacilli (tuberculin, mallein). Thus far only two, or possibly three, such bacteriological tests can be said to be in general use throughout this country, *i.e.*, the search for the tubercle bacillus in sputa; the search for diphtheria in the throat, and possibly the agglutination test for typhoid. Other such aids to diagnosis which seem likely to come into more general use are the examination of the blood, the sputa, the urine, the feces, the cerebrospinal fluid, the urethral, the vaginal, the uterine secretions, the nasal, pharyngeal and conjunctival secretions. Next to typhoid, Malta fever seems at present the disease in the diagnosis of which we are most helped by the agglutination tests. To other diseases, the diagnostic assistance of the agglutination reaction has not been extended. Individual observers have reported success in the attempt to apply the serum tests to diagnosis of tuberculosis and croupous pneumonia, but the results have not been extensively confirmed. To a limited extent we are able to reverse the use of the agglutination test; instead of using the well identified bacillus to test the body-fluid of a doubtful case, we can use the body-fluids of a well identified case to test a doubtful bacillus. Of the diagnostic use of tuberculin it is only necessary to say that despite the warnings of Virchow, it has passed into general use and deserves to be utilized much more widely still. The few who object to its use are for the most part those who have not tried it. The use of mallein is well established. Statements regarding prognosis are apt to present an unrivalled material for the study of the art of hedging. Bacteriology is helping us to make our prognoses less meaningless. The clinicians realize how difficult it is to interpret the results of bacteriological examinations. For example, to draw the properly limited inference from the announcement of a positive Widal reaction, to be enough and not too much alarmed by a positive tuberculin reaction, or by the finding of Klebs-Loeffler bacilli in a patient's throat. Especially is this true where relatively indefinite quantitative expressions enter into the bacteriologist's report. Only he who makes the test can really appreciate what is meant in a given case by such phrases as "Very numerous tubercle bacilli, very virulent streptococci, very motile organisms, very numerous malarial organisms, etc."

The municipal laboratory of the city of Boston now offers to examine for physicians material suspected as coming from any of the following diseases: Typhoid, tetanus, tuberculosis, rabies, diphtheria, malaria, glanders, influenza, pyogenic organisms, gonorrhea.

Bacterio-Therapeuties with Especial Referenee to Tubereulosis.—Dr. E. R. Baldwin of Saranac read a paper with this title. The author dealt with the various uses of bacteria and serums in the prevention and treatment of diseases with a more detailed account of those in tuberculosis. Living bacteria are little used except in vaccination for variola and anthrax. Dead cholera, plague, and typhoid bacilli are useful in prevention, but irrational in treatment. Diphtheria and tetanus are as yet the only conspicuously antitoxic serums of practical value. Streptococcus, pneumococcus, cholera, typhoid, plague and recurrent fever serums are either bactericidal or bacteriologic and of greater value in immunization than treatment. There are many extracts of tubercle bacilli under the general name of tuberculin, which the author enumerated and described. No permanent immunity is produced by any of them, although the new tuberculins have some immunizing power in animals. The method is not applicable to man, nor safe, because likely to produce chronic poisoning, even in healthy subjects. Research at present aims to discover and utilize the mechanism of relative immunity produced by injections of bacillus substance. The nature of the tuberculin reaction is of importance. Of the various theories promulgated, that which assumes a ferment action, chiefly produced by secretions from leucocytes, is most in line with present knowledge. Many bacterial extracts, nucleins and digestive albumoses excite the same reaction as tuberculin produces. Tuberculin used therapeutically has only a limited application, and as it does not immunize for any length of time, it may not be better than other substances that can produce local hyperemia. The production of local hyperemia is rational in lupus, tuberculous peritonitis and, to a limited extent, in pulmonary tubercu-

losis. Serums are not yet successful as to antitoxic properties. They may be bacteriologic or bactericidal. There is still hope for some efficient serum or extract of tissues, although possibly it may not be antitoxic.

Etiology of Malarial Fever.—Prof. William S. Thayer of Baltimore read this paper. He was of the opinion that the disease was acquired through the gastro-intestinal tract, especially by drinking water; through inhaled air; and by the bite of insects. The experiments of Celli, Marino, Zeri, Grassi and Filetti were strong evidence against the idea that the disease might be acquired through the gastro-intestinal tract; while a careful study of the literature as well set forth by Norton revealed the utter lack of evidence in support of such an idea. With regard to the theory that the disease was acquired by inhaled air, it could only be said that while such general facts spoke in its favor, no positive evidence in its support had ever been adduced. That the disease might be acquired through the bites of insects, especially of mosquitoes, had become an attractive hypothesis. It then may be considered as proven, that the malarial parasite possesses an extra-corporeal cycle, which is completed in the stomach wall of mosquitoes of the genus Anopheles, and that members of the genus Anopheles are capable of transmitting malarial from infected to non-infected individuals. The author then went over the bites of insects indigenous to certain localities in relation to the pathological effects, and especially referred to the class of mosquitoes which infect the suburbs of Baltimore.

Bacteriology of Dysentery.—This paper was read by Prof. Simon Flexner of Philadelphia. He said in part: There are few subjects in medicine that have attracted more attention than dysentery. Its history dates from the earliest written records and its ravages, unlike those of many of the pestilential diseases, have continued perfectly unabated to the present day. The most ancient writing upon medicine—the Papyrus Ebers—contains allusions to dysentery: the oldest Indian medical writers refer to it under the name atisar, while Herodotus speaks of its prevalence in Thessaly. Hippocrates, however, was the first to regard dysentery as an independent disease. I should hesitate to bring before this audience a subject so time-worn were it not for the fact that the nature and more especially the etiology of dysentery are among the problems which still await a satisfactory solution.

The imperfection of our knowledge of the nature of dysentery is not due to lack of opportunity for or of energy in its study. The literature contains some of the most distinguished names among clinicians and investigators, thanks to whose efforts its clinical history, its epidemiology and, to a less extent, its pathological anatomy have received partial elucidation. Nor has the disease in the past quarter of a century escaped the attention of the bacteriologists, although it must be confessed that the results of somewhat extensive studies along these lines have been far less conclusive than might have been predicted. Given a disease that is never entirely absent from temperate and tropical regions, that appears with epidemic severity, that permits of easy access to the *materies-morbi,* one would certainly have been tempted to predict that the success achieved in so many other and apparently no less difficult fields, would probably be repeated. That the attempt to establish a common etiological factor for all cases of dysentery has thus far failed, this audience need not be reminded. That this failure to emphasize the existence of several pathological states for which the term dysentery is employed merely as the collective designation need not be defended here. But that these conclusions regarding the disease may after all not be in keeping with the facts is at least open to suspicion. When we recall the protean nature of other infectious diseases, among the most common of which are tuberculosis and typhoid fever, there can be no *a priori* objection to the hypothesis that the causative agency of dysentery need not necessarily vary for each of the many types of the disease that have, from time to time, been distinguished. For the purpose of my inquiry I shall consider briefly the clinical and pathological types. That the lines of demarcation between the several clinical and pathological types should be inaccurate is not a matter of wonder. Both the beginning and the end of any given instance may vary very widely and the symptoms and lesions of cases arising sporadically in temperate climates may agree with those of dysentery occurring endemically in the tropics or epidemically in both localities. The terms "catarrhal," "tropical," "epidemic" and "diphtheritic" are far from signifying sharp-cut entities. The clinical manifestations and pathological lesions of the catarrhal variety occur in all kinds of dysentery and in all places where the disease prevails. Ever since the time of John Hunter there have been those who, upon pathological-anatomical grounds, have separated the endemic from the epidemic disease, and the line has been even more sharply drawn during the past decade, since the discovery of the ameba coli in its relations to tropical dysentery. But the distinction between tropical dysentery, which is characterized by ulceration and thickening of the intestines—especially the colon, the lesions beginning in the submucous coat of the gut—from the epidemic disease in which a false membrane exists, usually associated with ulceration without any primary involvement of the submucosa, is far from sharp and constant. In this country diphtheria has not been commonly observed in the ulcerative and amebic form of dysentery, while in Egypt, the two pathological conditions are not infrequently found together.

Second Day—May 2d.

The first order of business was the voting on the resolution, which was unanimously carried, reading as follows: For the appointment of a

committee of three, with full power to draw up and execute on behalf of the Congress of American Physicians and Surgeons, a memorial and petition to the Congress of the United States, asking that charitable, religious and educational institutions be relieved from such provisions of the War Revenue Act of 1898 as impose taxes on legacies left to such institutions, and to take such other action as may, in their discretion, seem desirable in securing such relief.

The following resolution by Dr. W. W. Keen, of Philadelphia, was unanimously carried:

Whereas, the medical profession employs various kinds of exact measuring apparatus, particularly clinical thermometers, ureometers, lactometers, and volumetric apparatus; and

Whereas, the physician should be able to obtain a written official guarantee of the accuracy of such apparatus; and

Whereas, no bureau has been established by our government for this purpose, necessitating the importation of such apparatus from countries possessing standardizing bureaus; therefore be it

Resolved, that the Congress of American Physicians and Surgeons heartily endorse the movement now on foot establishing such a standardizing bureau where such work and other equally important work may be undertaken.

Resolved, further, that a copy of these resolutions be forwarded to the Secretary of the Treasury, to the President of the Senate, to the Speaker of the House of Representatives, and to the Chairman of the House Committee on Coinage, Weights and Measures.

Sociological Status of the Physician.—Dr. Clarence J. Blake of Boston read this paper. The author said that the range of sociology, in its modern form, may be said to extend from investigation of the power value of psychic phenomena in the unit to consideration of physical economics in the mass. The original ideas of society as the product of extrinsic causes or of society as a force aggregation upon a materialistic basis, have gradually given place to a recognition of the continuity of the ethical idea in an aggregation of human units the majority of whom are relieved, in whole or in part, from the demands incident to a primitive struggle for existence. It is precisely at this point in the development of sociology that a member of the body politic, who has long existed and who has indeed for several centuries had a definite sociological status, becomes an increasingly coöperative factor.

The science of society which has come in the growth of its responsibility to the human mass to find the need of a more accurate study of the entity of the human unit turns to the doctor of medicine for advice and counsel. To the members of the medical profession, whose devotion primarily to the needs of the unit, leads them to concentrate their energies upon a succession of individuals and who consequently find themselves isolated more or less from the social community and placed apart as specialized workers, the newer and broader sociology brings not only the stimulus of association and sympathy but larger opportunities for the exercise of their usefulness. As a natural result of this approximation, appreciation grows, barriers of prejudice are broken down, the conventionalities of self in which pessimism is nourished disappear and men of different walks of life come to understand each other better, in the light of a common purpose to helpful ends. The sociological status of the physician, therefore, at the present time, may be said to be his standing in regard to an extensive movement in behalf of the study of human relationships with a view to a truer comprehension of their normal basis and to their betterment.

Before proceeding to a consideration of the effectiveness of the doctor of medicine as a part of the social organization exhibited through the medium of the institutions with which he is particularly related and of the other duties of which he is capable and which lie before him, it will be well to consider briefly the character of his professional training and its reactionary effect upon himself as a man and citizen. Of all special educations that of the science and practice of medicine, when it is of the best quality, is the most exacting and makes the largest demand upon the staying power of the student; it is longer in duration, more confining, but requires more intense application than the corresponding courses which lead to a degree either in law or divinity and affords a larger suggestive opportunity for collateral scientific reading. It implies in its beginning, the combating of natural repugnancies and, in its continuance, a ceaseless struggle against the mentally depressing influence of daily contact with disease and dissolution, it challenges lofty sentiments and lays bare the framework of cherished emotions; on the other hand, it demonstrates truth and gives the foundation for a faith which, although usually silent and often circumscribed, nourishes the optimism necessary to this vocation and helps the doctor to regard the affairs of life in the light of their importance, not to himself, but to the individual whom for the time being they most concern.

That the "outward profession of a faith" is not usual in the medical profession is not due to the lack of this quality, but rather to the reluctance to make public expression on the part of men whose life is, in its practical exhibition, largely confidential and who, moreover, have especial opportunity to give utterance to the spirit within them in human contract work. To the claim that medical education furnishes the material for a deep and lasting faith in a creating and sustaining power may be added the claim that it tends to beget that sense of reverence of which Benjamin Kidd says, "It is a preponderating element in the type of character which the evolutionary forces at work in human society are slowly developing and with which are tending to be closely allied the qualities of great mental energy, revolutionary enterprise, powers of prolonged and concentrated application and a sense of single-minded devotion to conceptions of duty."

In the very beginning of his studies the medical student is brought into investigatory relationship with that which he has heretofore thought of as an entity, a being, a mystery, and which, now put into his hands for demolition, he finds to be a most wonderful and delicately constructed machine, in the study of which he may be said to pass through much the same process of mental evolution as that attributed by Professor Giddings to primitive man. He is lost in marvel at the compact arrangement of muscular tissues; regards, as might the explorer of a buried city, the system of canals which carry quickening fluid to the outermost circumvallation and of drains into which are cast waste matters to be discharged without the walls; while the glistening white lines of nerves, sending their branches in a network between muscles and under and over canals and drains, reveal to him the suggestion of a system for the communication of intelligence and the issuance of governing mandates to which the combined telegraphic and telephonic services of the greatest city built by human hands have no comparison in relative extent or perfection. There is probably no point in his career of so much initial portent as that in which the student, in the dissecting-room, for the first time lifts the wet sheet from a face that he has never known, but behind which there dwelt and through which there have been expressed all that emotion and desire can crowd into the compass of a human life; it is a period in which he either consecrates himself or turns back; if he be honest he does one or the other, if he be a pretender he may, it is true, continue and complete his medical school course and go out into the broader school of work, but without the consecration he will inevitably fail of his highest possibilities as a physician.

The impress which is made by the study of anatomy upon the truly thoughtful man cannot but be emphasized in the physiological laboratory where the student learns the values and uses of the different parts of the human machine and finds the answers to the questions which the previous study of the structure of the silent body has evoked. Here and in the associated laboratories, he learns the chemical processes of the body in health and disease, the supplementary relationship of the different organs, the provision for their maintenance and repair and comes to recognize and to know the functions of the microscopic organisms with which the body teems. Carrying with him the lessons born of research, he next passes into the wider school of clinical teaching and learns at the bedside that he has to study something more than the disease, and that to render the fullest meed of service as a physician he must come to know, patiently, tenderly and, in the broadest sense, sympathetically, his brother man.

From an economic standpoint the hospital may be defined as an institution in which capital and skilled labor combine to provide such members of the community as are temporarily disabled and without means of support, with the maintenance and care which shall fit them to become again self-supporting and active community factors. The hospital of to-day is something very much more than a mere repair shop, it is a school full of object lessons in the application of those qualities which are the uprights, the girders, and the binding rods of the modern social structure; in the first place, it is the most absolutely clean of all human habitations, and the present splendid successes of surgery in the amelioration of suffering and the preservation of life are due not only to the application of trained skill and intelligence, but to its operations under conditions of absolute sterilization which are microscopic in their minutiæ.

At the conclusion of Dr. Blake's paper, President Bowditch came forward and said:

"Now, gentlemen, it is my pleasant duty to ask your attention to our honored ex-President who has cultivated the fields of medicine and literature with equal success, and who has kindly consented to express himself in his own charming verse on the "Evolution of the Physician."

In part, Dr. S. Weir Mitchell spoke as follows:

"Mr. President and Fellow Members of the Congress: I will say a word in explanation of the unusual fact of my appearance here. It is perfectly well-known, I venture, that never before in the history of medicine has a Congress been addressed in verse. For this novelty, you may thank the committee of the Congress, and my friend, its President."

At the conclusion of the reading of the poem, Dr. Mitchell was greeted with prolonged applause and was enthusiastically congratulated. The poem was a fine contribution to literature and was delivered with freedom and appropriate gesture. The doctor's honorable, dignified and humanitarian station in life was described in glowing language. The priests disagree, but doctors extend the universal hand of fellowship and goodwill. One gem of the poem is as follows:

What sense of pleasure won that helping hand,
You best can tell, you best can understand;
Who looking back across your busy years,
Know what your hands have spared of pang and tears.

There was prolonged applause when the lines rang out,

One bugle-note or one battle-call,
One watchword—DUTY—that is all.

Congress adjourned until evening when an address was delivered by the President on "The Medical School of the Future," which appears in full in this issue of the Medical News.

Hospital Bequest.—The Germantown (Pa.) Hospital and Dispensary is to receive $58,000 to be known, from the name of the donor, as the Lambert Lare Endowment Fund.

AMERICAN SURGICAL ASSOCIATION.

Twenty-first Annual Meeting Held at Washington, D. C., May 1, 2, and 3, 1900.

First Day—May 1.

Perforating Ulcer of the Duodenum.—The scientic business of the American Surgical Association was introduced by the President, Dr. Robert F. Weir, of New York, who read a paper upon the above mentioned subject, which is published in this issue. (See page 690.)

Non-Perforating Gastric Ulcer.—Upon this theme Dr. Wm. L. Rodman, of Philadelphia, read the first paper in a series upon surgery of the stomach. In the treatment of no other disease is there greater need for a perfect understanding between physician and surgeon. Since the worst complications may develop unexpectedly, there is but one safe rule to follow, and that is for the physician to treat all patients having gastric ulcer, either in a hospital or at their homes, in conjunction with a surgeon. Three-fourths of all cases of non-perforating gastric ulcer can be cured by medical means; but if success does not follow medical measures in four or five weeks, surgical relief should be sought. Excision of the ulcer is the ideal treatment in the face of uncontrollable vomiting, suspected malignant degeneration, etc., but gastro-enterostomy gives almost as good results, and is to be preferred in all cases in which severe hemorrhage follows from a posterior situation of the ulcer. The presence of firm adhesions or of a multiplicity of cancers makes partial gastrectomy particularly dangerous. At its best, excision has a mortality of 15 per cent.

Dr. Rodman does not advise operation for hemorrhage either during the first attack or during recovery from it. Only 8 per cent. of patients who bleed from the stomach die. Even in a second hemorrhage it may be advisable to wait. But the published records of cases show that delay after a second severe hemorrhage has more than once cost the life of the patient. The results of operation in acute hemorrhage are encouraging and are growing better each year. Robson's tables, with a smaller number of cases, show a mortality of 64 per cent. after operations for acute hemorrhage; but some cases are incorrectly quoted by him. Dr. Rodman made a more exhaustive search and found 31 such operations with only 11 fatalities—a mortality of 35 per cent. Surely not a prohibitive mortality since most of the patients operated on were in desperate condition. Far better results have followed operations upon patients suffering from constantly recurring small hemorrhages; the mortality being only 16 per cent. Various operations have been performed, but gastro-enterostomy has been and is likely to remain the operation of choice, because one can never be sure of finding the bleeding point, even when the stomach is opened and examined in a good light; and one can never be sure that there are not multiple ulcers. Such measures as ligation of the mucous membrane *en masse*, cauterization of the ulcer, ligation of the bleeding vessel and ligation of the main artery are too difficult or uncertain for general adoption. Pyloroplasty, once in favor, is steadily losing ground before gastro-enterostomy, which has been performed for chronic small hemorrhages 12 times without a single death.

Perforating Ulcer of the Stomach.—The second paper in the series upon surgery of the stomach was read by Dr. J. M. T. Finney, of Baltimore. Success in operation depends on early diagnosis. There are no distinctive symptoms of impending perforation, but the perforation itself is attended as a rule by well-marked phenomena. Sudden sharp pain in the upper part of the abdomen, often accompanied by vomiting and symptoms of shock, localized tenderness and marked rigidity of the abdominal muscles with retraction have been generally noted. Later, there is gradually increasing distention, possibly with free fluid in the peritoneal cavity. Another important symptom, to which thus far no attention has been paid, is the development of marked leucocytosis. This condition of the blood is never seen in connection with gastric ulcer except after perforation, or a severe hemorrhage, or a sudden change from absolute rectal feeding to feeding by the stomach. This development of leucocytosis is an important symptom, and should always be looked for, but too much reliance must not be placed upon it as at times it has been found wanting. The reader warned against the use of opium before operation, because it may cloud the diagnosis and also prejudice the chances of recovery. The operator should not delay operation on account of shock, for the operation is calculated to relieve the cause of shock, and the anesthetic itself has a beneficial stimulating effect. In doubtful cases one should open the abdomen to establish the diagnosis, using for the purpose cocaine anesthesia, which may be supplemented, if the patient complains, by a few whiffs of ether or chloroform. The surgeon should systematically explore the stomach, passing from the cardiac end over the anterior wall to the pylorus, and then along the lesser curvature; and then, lifting the stomach, he should examine the posterior wall. Dr. Finney insisted upon the necessity of thorough cleansing of the intestines, coil by coil, and of the whole peritoneal cavity by irrigation and wiping with gauze pledgets. Adhesions should be respected. If the operation is performed early and the peritoneum is thoroughly cleansed, the abdomen may be closed. In doubtful cases it is better to drain. Post-operative distention, most marked when opium has been freely given before operation, should be treated by calomel in broken doses followed by salts, high enemata of glycerine and water or glycerine and oil. Washing out the stomach and the application of the Paquelin cautery to the abdomen are, also, useful measures.

Prognosis depends upon several factors: The condition of the stomach, empty or full when perforation has taken place; the interval between the last meal and the perforation; the time elapsing between the perforation and the operation; the number and size of perforations; the position of the patient at the time of perforation; the perfection of the operative technic, and, finally, on the nature of the infectious agent, whether streptococcus pyogenes or not.

Malignant Diseases of the Stomach and Pylorus.—Dr. W. J. Mayo of Rochester, Minn., urged the necessity for an exploratory incision in every instance in which cancer of the stomach is suspected. If the surgeon waits for a certain diagnosis he will be too late. It has been suggested that the same principles of thorough extirpation which are giving such good results when applied to cancer of the breast, should be applied to gastric cancer; but it is well to remember that glands may be enlarged from septic causes. In more than half of the 28 patients upon whom Mayo has operated for non-malignant gastric dilatation, enlarged glands were palpable, due to accompanying gastritis. Many patients die of cancer of the stomach without glandular involvement, and even if the glands do become involved their situation is such that their removal is practically impossible. Malignant disease of the stomach has a peculiar depressing effect on the patient. The nutrition is bad, and the healing power is greatly reduced. Ascites even in a limited degree is a contraindication to operation. The diagnosis even after the abdomen has been opened is not always clear. There are no definite universal signs upon which to base a diagnosis. Four of Czerny's patients upon whom gastro-enterostomy was performed, lived so long as to make it pretty certain that the diagnosis of cancer was an error. If the disease is cancer, too extensive for extirpation, yet not requiring a palliative operation, the abdomen should be closed by the Halsted method, which will allow the patient to get about in a few days and to leave the hospital in a week. Complete gastrectomy is probably destined to become a most valuable operation, but this the future must finally determine. Operations confined to the pyloric end of the stomach have been largely practiced, and are on the whole unsatisfactory. The late diagnosis has been in part responsible. Surgeons in view of the absolutely unfavorable prognosis have sometimes performed operations too serious for the strength of their patients. Kocher's operation, closing the wound in the stomach and forming an independent anastomosis between the duodenum and stomach, has been generally adopted as the safest pylorectomy. Gastro-enterostomy is the most generally useful palliative operation in conditions of pyloric stenosis beyond radical treatment. Two methods of gastro-enterostomy have stood the test of time, simple suture, and the Murphy button. The results published by the advocates of the two methods are about the same, and depend apparently more on the operator's skill than on the method. Surgeons are also divided as to the relative merits of an anterior posterior-enterostomy (Wolfler's method), or posterior gastro-enterostomy (von Hacker's method). By the latter procedure the posterior wall of the stomach is reached by traversing the cavity of the lesser peritoneum. It is claimed for this method that the food passes more readily downward, that a button if one is used is less likely to drop into the stomach, and that regurgitant vomiting of bile and pancreatic juice is less frequent. These are all good claims if true, but a study of the published cases of both methods shows little difference in the after effects, and since the anterior method is simpler Dr. Mayo prefers it. The point chosen for the anastomosis should be about an inch above the lower margin of the stomach, and as near the pylorus as possible, yet it must not be near enough to be encroached upon by the disease. When anastomosis is complete, the weight of the loop draws the stomach over until the point of attachment is the bottom of a funnel. Dr. Mayo has performed this operation thirty-one times, and has seen regurgitant vomiting in only two instances, both of the patients in question being sufferers from malignant disease. In all of these patients the Murphy button was used without supplementary suture. There were three deaths after eleven operations for cancer, and one death after twenty operations for benign trouble.

Second Day—May 2d.

Benign Obstruction of the Pylorus.—Dr. F. Kammerer of New York divides cases of benign obstruction into those which are congenital and those which are acquired. The latter demand the aid of the surgeon. The pyloric stenosis may be due to ulcer, benign tumors, syphilis, gall stones (by secondary inflammation). Stenosis may also be due to hyperchlorhydria. This last affection is considered by some to be a functional neurosis. The result of spasm is stasis and decomposition of food. Hypersecretion is the natural result, which in turn causes firmer contraction of the pylorus. When the abdomen is opened and the stomach is relaxed, no evidence of spasm of the pylorus may be visible. However, spasm has also been observed during operation. Various attempts have been made by means of ingested gutta percha balls and elastic sounds passed by the mouth to dilate the contracted pylorus. Ulcer is a contraindication for such treatment, which, moreover, in no case seems to have had any permanent good effect. Excision of the pylorus for ulcer or benign stenosis is an operation with a mortality variously estimated at from 18 to 34 per cent. Resection when no ulcer is present seems somewhat less dangerous than in the presence of an ulcer, but it is an operation which is being rapidly abandoned. Divulsion carried out either through an incision into the stomach or by invagination is another operation which has no future, for the reason that pyloroplasty and gastro-enterostomy have many ad-

vantages not possessed by the older operations. According to published reports of cases the mortality of both pyloroplasty and gastro-enterostomy when performed for benign stenosis is about 15 per cent.; but writers sometimes do not include those fatal cases in which pyloroplasty is attempted and on account of adhesions has to be abandoned for a resection of the pylorus; and, moreover, the newest reports of gastro-enterostomy give a far lower death-rate to this operation than earlier statistics. The presence of extensive adhesions must be considered a contraindication to pyloroplasty, for, although division of adhesions alone has sometimes cured a patient, broad adhesions usually reform, and an inflamed gastric wall is not suited to suture. No such complications ever prevent the surgeon from the proper carrying out of gastro-enterostomy. The immediate results of pyloroplasty are usually good. There is a restitution to normal of the affected parts. Gastro-enterostomy produces an abnormal condition and may be followed by fatal regurgitation. This is more common in carcinomatous than in benign cases and seems to occur more frequently after anterior than posterior gastro-enterostomy. The enforced recumbent position of the patient adds to the difficulty of the stomach in emptying itself, and a broad line of suture seems to flatten the intestine against the stomach and tend to obliterate its lumen. If a posterior gastro-enterostomy is performed and Murphy's button is employed the evils of regurgitant vomiting may be avoided. Kammerer has performed such an operation eleven times in the past two years (nine of the patients having cancer) and in no instance has there been any evidence of regurgitation. Some Continental operators of large experience, such as Carle and Czerny, are quite of the same mind. Doyen performs a posterior operation suturing without a button; but Mikulicz, who formerly advised a posterior operation with the button, has returned to the anterior operation with suture alone. In the use of the button, one or two simple sutures to fix each half in its appropriate viscus are better than purse-string sutures, which cause a puckering of the coats and so make an even pressure and necrosis uncertain. The button may drop into the afferent limb of the jejunum or into the stomach, but trouble from this cause has rarely been mentioned. Constriction of the colon by the anastomosed intestinal loop, or the reverse, is a complication which can hardly occur with posterior gastro-enterostomy as the normal relations of these organs are scarcely altered. In comparing the remote results of pyloroplasty and gastro-enterostomy, the frequency of relapse must be first considered. After the former operation relapse may be due to a further formation of pyloric cicatricial tissue, or to the fixation of the pylorus in an unfavorable situation by adhesions, or to progressive gastric atony, while relapse after gastro-enterostomy may result from contraction of the orifice, which is rare and has been attributed to inaccurate suture of the mucous membrane. In conclusion, it may be said that in well-selected cases the results of pyloroplasty, both immediate and remote, are as good as those of gastro-enterostomy. In cases in which there is no fixation of the pylorus, and not much inflammatory thickening, nor too much dilatation of the stomach nor weakening of its walls, pyloroplasty is as safe as posterior gastro-enterostomy with the button; safer perhaps than the same operation by suture. It is free from the intestinal complications of the latter, to which allusion has been made above. But it has one regrettable feature—an uncertainty of result, and, when the dangers of two operations are about equal and one of them offers greater assurance of success in every case, the latter should always be the operation of choice.

Gastric Dilatation; Gastroptosis.—Dr. B. F. Curtis of New York said that the surgeon need not concern himself with fine distinctions as to the exact outlines of the normal stomach. It is at least certain that in normal individuals the pylorus is so sheltered as to be nearly out of reach of the palpating fingers, while the lesser curvature is quite so. When these parts can be felt therefore, a condition of gastroptosis exists.

Gastrectasia is an enlargement of the stomach combined with motor insufficiency, that is to say, a relative insufficiency, a disproportion between the muscular power and the resistance to be overcome. All obstructions at the pylorus are not followed by gastrectasia, because in many cases the muscular hypertrophy is sufficient to overcome the pyloric resistance and empty the stomach.

Atonic dilatation is often associated with gastroptosis. The weight of an enlarged stomach may stretch its attachments and cause its descent, and, on the other hand, gastroptosis may obstruct the escape of food and cause an obstructive dilatation. In the majority of cases gastrectasia and gastroptosis coexist because they have a common origin affecting the general nutrition of the body, and in which there is often a strong nervous element.

The symptoms of atonic gastrectasia are a feeling of fulness and weight after eating, without pain. The appetite is often maintained and there is great thirst for water which is not absorbed by the stomach and its passage to the intestine is delayed. Other symptoms are headache, dyspnea, dizziness, constipation (occasionally diarrhea), marked emaciation, a very slow pulse, and scanty urine. There may be eructations of gas, with or without vomiting. Inspection, palpation and percussion will show an enlarged stomach. The stomach-tube will show a retention of food for a much longer than normal period, and motor insufficiency can also be demonstrated by testing the urine after ingestion of salol. The size of the stomach should be proved by inflating it with air or by the bicarbonate of soda method.

The prognosis of extreme atonic gastric dilatation is not favorable, but the changes take place

more slowly than in obstructive dilatation. Medical rather than surgical treatment is usually indicated; but the latter should be resorted to when the former fails to keep the patient from continuous loss of weight and strength. Either gastroplication or gastro-enterostomy may be performed.

Gastroplication is an infolding of the walls of the stomach. It is contraindicated if pyloric obstruction exists, and is unnecessary if such an operation as pyloroplasty is done at the same time. It has, therefore, a limited field, and less than thirty cases have been reported. In many instances the subsequent condition of the patients so operated upon was not given, while in some instances the operation was ill advised. It may be safely inferred, however, that the operation has only a small mortality, and that in suitable cases it produces good results. Several methods of folding in the stomach have been suggested, Weir's plan being perhaps the best. He makes several longitudinal folds, stitching each separately. The rival operation is gastro-enterostomy with a mortality somewhat higher (10 per cent. in non-malignant cases), but which has the distinct advantage of relieving the patient, even although pyloric obstruction is present; while a gastroplication can hardly be expected to give relief, if pyloric obstruction coexists.

Gastroptosis is a sinking of the lower portion of the stomach, as shown by a change in the position of the lesser curvature. Meinert claims that gastroptosis is present in more than 80 per cent. of women. To a considerable degree it may exist without symptoms. These develop in proportion to the amount of pyloric obstruction present. Palpation and inspection of the abdomen may give a suspicion of gastroptosis, but for an accurate diagnosis it is necessary to dilate the stomach with gas or air. Then the lesser curvature and the pyloric portion come out clearly. It is only recently that this condition has been met by surgical measures. The indication is clearly to support the stomach from above, and Duret and, after him, Rovsing have sutured the anterior wall of the stomach to the parietal peritoneum close up to the diaphragm, and have succeeded in relieving their patients. This operation is called gastropexy or gastrorrhaphy. Various stitching procedures have been successfully carried out by Treves, Byea and others, in order to shorten the supports of the stomach, or to attach it to parietal peritoneum as high up as possible.

In conclusion the speaker said that improvement is not difficult to bring about whether one secures the liver only, sutures the stomach itself, or the mesocolon to the abdominal wall, or shortens the gastrohepatic omentum, or finally, removes a segment of the abdominal wall. The condition is usually a complex one, and probably a simple gastrorrhaphy will not be sufficient, but should be assisted by right nephrorrhaphy, hepatorrhaphy, and in some cases by the Depage-Hannecort operation. In women similar supporting operations on the genital organs will also be necessary to assure a good result.

Hour-Glass Contraction of the Stomach.—Dr. F. S. Watson of Boston said that this lesion has a surgical history of only ten years—and the principle of anastomosing the two portions of the stomach was first carried out by Wölfler in 1894. Since then anastomosis has been carried out in one form or another many times. Altogether thirty-five operations upon an hour-glass stomach have been published. The speaker described a case on which he had successfully operated. His plan was to suture together the parts to be anastomosed, before the stomach was opened. Communicating incisions were then made, which of necessity exactly coincided, and were sutured internally. The extra incision in the stomach was then closed. The choice of method must depend on the conditions found. In some instances gastro-anastomosis is not practicable because it would bring too great a tension on the parts. Gastro-enterostomy fails to utilize the digestive capabilities of the pyloric half of the stomach, and if the cardiac portion of the stomach is atrophied, this loss of the pyloric portion will be serious—a plastic operation is in many cases technically inadvisable while a resection of the constricted portion is too dangerous for practical use. Whatever operation is chosen, the surgeon should not forget the advantage of freeing adhesions—as this of itself has been known to cure many annoying symptoms.

Diagnosis of Cancer of Stomach.—Dr. J. C. Hemmeter of Baltimore said that the only diagnosis of cancer of the stomach which is of interest to the surgeon, is an early diagnosis; that is a diagnosis before the symptoms of cancer have appeared. Such surgeons as Czerny, Rindfleisch and Kraske oppose operation on gastric cancer after a tumor can be made out. Against an early diagnosis are first the indifference of the patient and unfortunately many times of the physician, before well marked symptoms arise; and second the fact that chemical and microscopical tests of the gastric contents themselves take so much time. The absence of hydrochloric acid is not a reliable sign, for patients may die of cancer with hydrochloric acid in their gastric contents. The presence of lactic acid is merely due to stagnation and while a valuable sign it occurs too late to be of service in making an early diagnosis. The same is true of the Oppler-Boas bacillus. The pylorus is so situated that a tumor of it may grow to a considerable size and still be not palpable. Electro-diaphany and the X-rays are valueless for early diagnosis. Gastroscopic examination is dangerous. Curetting the surface of the stomach is a newer method of diagnosis, which yields sure evidence if a typical bit of tissue can be secured; but cancer of the stomach must already have progressed to a certain degree before a bit of tissue can be obtained with a weighted stomach tube, which is the harshest instrument which Hemmeter considers safe to use. This means of diag-

nosis is still undeveloped, and as yet the early diagnosis of carcinoma of the stomach can only be made with certainty in a few cases. Although surgical treatment of cancer of the stomach is at present the best treatment we know of, it seems certain that it will some day give way to a form of treatment, to be discovered by the Pasteurs, or Klebs, or Kochs of the future who shall show us a method of treatment which shall cause the cancer to melt away as the antitoxin treatment causes the diphtheritic membrane in a child's throat to disappear.

Gastric Functions before and after Gastro-Enterostomy.—Dr. Charles S. Fischer of New York presented the results determined by him by following up for some years four cases in which gastro-enterostomy was performed for non-malignant conditions. The speaker said that only by observations extending over periods of months and years before and after operation can definite conclusions as to the changes brought about by the operation be made. The two functions of the stomach which are especially concerned are its secretion of hydrochloric acid and its motility.

In one case in which gastro-enterostomy was performed for hyperacidity, pyloric obstruction and dilatation, the immediate results were excellent. The hyperacidity, however, progressively increased, and two years after operation it was greater than ever. The motor conditions of the stomach were much improved, and the stomach was found empty upon lavage within the necessary time limit. A second case was similar up to the time of operation. This patient also was much improved by the operation, but fourteen months later it was found that the change in hyperacidity did not keep pace with his general improvement. In this case slight atony existed fourteen months after operation, which could be traced to improper hygienic surroundings. In the third case the hyperacidity was purely functional. The pyloric stenosis and slight dilatation were secondary. After operation examinations showed that hyperacidity sometimes came on as a result of mental excitement, and sometimes was absent. The fourth case was followed for four years prior to operation, during which time simple gastric dilatation, as a result of atony, developed. At first there was nervous dyspepsia with varying acidity and a tendency to gastroptosis. A year later the condition had changed to subacidity and atony began to show itself. From that time there was progressive weakness and dilatation of the walls of the stomach and relaxation of the abdominal walls, and the right kidney became movable. The patient's general health was much improved by the operation, but one year later the gastric dilatation still existed and the subacidity had progressed to a fair state of achylia. The motor functions appeared normal. These cases represent three distinct types of benign chronic gastric trouble: Primary pyloric obstruction with secondary hyperacidity and dilatation (cases I and II); primary functional hyperacidity, with secondary pyloric spasm and dilatation (case III); and primary neurotic atony, with secondary subacidity and dilatation (case IV). The consideration of these results, and especially of the results in the third and fourth cases, is of the greatest value to the physician, for there are cases in which operation is one of expediency and not of necessity. In case III, after operation, there was a general improvement in the health of the patient and a considerable gain in weight, and no dyspeptic symptoms. Yet in one year the changes in the mucous membrane progressed as far as to give a condition of achylia, which cannot possibly be explained on the basis of continued imitation due to food stasis, for the stomach emptied itself properly. The conclusion is obvious that hypertrophic or atrophic changes of long duration may be progressive after operation. In those cases in which enlargement and impaired muscular activity are relative and due to obstruction, gastro-enterostomy, by removing the obstruction, gives the stomach an opportunity to return to its normal condition. Gastro-enterostomy has a beneficial effect on the action of the intestines. In the first three cases the constipation was due to the pain caused by the pyloric spasm—a reflex constipation. It was entirely relieved by operation. In case IV the constipation was atonic, alternating with fermentative diarrhea. In this case, after operation, the stools became normal and regular, as a result of improved nutrition.

Adhesions of the Stomach.—Dr. A. T. Cabot of Boston said that adhesions are chiefly of significance when situated about the pylorus. Sometimes the digestive disturbances are spread out over the whole life of the patient, but usually they come on in distinct attacks like attacks of gall-stone colic. Vomiting is prominent, and is probably merely a result of the pain. The latter may be spasmodic or lancinating. The pain may extend around the body as a girdle. Sometimes the digestion in the interval between the attacks of pain is good, sometimes poor. The severity of pain is usually the cause for operation.

Stricture of the Esophagus Following Gastrostomy.—Dr. F. S. Dennis of New York presented a patient who suffered from a stricture of the esophagus following typhoid fever. The patient was reduced almost to the point of starvation when a gastrostomy was performed. Since then he has gained flesh and is now in practically perfect health.

(To be Continued.)

ASSOCIATION OF AMERICAN PHYSICIANS.

Fifteenth Annual Meeting, Held at Washington, D. C., May 1, 2 and 3, 1900.

First Day—May 1st.

Truth in Medicine.—The president's address upon this subject was delivered by Dr. E. G. Janeway of New York (see page 690).

A resolution was carried asking that Congress remit the present war-tax on legacies to charitable, religious and educational institutions. It was pointed out that if Johns Hopkins had died during the past year, the University founded by him would have lost more than $1,000,000 in tax to the Government.

A resolution was passed to provide for the drawing up of a resolution to oppose the Senate bill introduced by Senator Gallinger which would limit animal experimentation in the District of Columbia. Surgeon-General Sternberg moved the appointment of a committee to carry on the opposition more effectively. This was adopted.

A paper on endocarditis in relation to other diseases to have been read by Dr. William Osler of Johns Hopkins, Baltimore, to whom the subject was referred for special treatment with the idea of evoking discussion, but Dr. Osler was unavoidably absent.

Diabetes with Low Specific Gravity.—Dr. James B. Herrick, of Chicago, read an account of some cases of diabetes with very low specific gravity despite the presence of sugar in the urine. Usually there is a ratio between the amount of sugar in the urine, the quantity of urine passed and its specific gravity, so that the severity of the mellituria may be estimated from the other factors, but this is not an invariable rule. Eichhorst has had a case of glycosuria with urinary specific gravity of 1008. Naunyn has seen cases with specific gravities from 1010 to 1015. As low as 1003 has been reported. These low specific gravities occur not only in the polyuria immediately preceding or following an acute exacerbation of the diabetes, but also at the height of the glycosuria. Various reasons are given. Low specific gravity occurs in weak patients, especially if they are taking large quantities of water. In one of Dr. Herrick's cases the patient was taking large daily amounts of a mineral water supposed to be curative for diabetes. His urinary specific gravity never reached 1020. In a case of obese diabetes in Dr. Herrick's practice the specific gravity was but 1004. To be sure there was no error, it was tested by several urinometers. The patient had been drinking beer excessively just before passing 24 ounces of urine and to this was due the low specific gravity. Cases of diabetes complicated by interstitial nephritis are especially apt to have low specific gravity of their urine. It is not enough then to look for sugar in the urine only when the specific gravity is above 1020. If interstitial nephritis is suspected or the patient is weak or takes liquids very plentifully, the urine should be carefully tested for sugar no matter how low the specific gravity.

Urinary Casts and Diabetic Coma.—Dr. Herrick has had three cases of diabetic coma recently, in all of which the development of coma was immediately preceded or accompanied by the presence of an abundance of granular casts in the urine. When the urine was allowed to stand for three hours about one-sixth of its volume was a gray or yellowish sediment almost entirely composed of these casts. Their number bears no relation to the amount of albumin present. They have been found 24 hours before an attack of coma. Their presence has been noted in the urine passed after exercise when three hours before they were not present and a little later symptoms of threatened coma supervened. In one case Dr. Herrick found them in the urine of a patient in whom diabetes had not been suspected, but who died 24 hours after the urinary examinations with typical diabetic coma. Naunyn does not think these casts pathognomonic of diabetic coma, but they may prove a valuable preliminary diagnostic sign. The kidneys seem to be overwhelmed by the toxins present in the circulation and the overtaxed epithelial elements give way with the production of these casts.

Uric Acid in Epilepsy.—Dr. James J. Putnam of Boston, in connection with Dr. F. Pfaff, has been repeating some observations made concerning the relations of uric acid to epilepsy. It was reported by Krainsky that before a seizure the amount of uric acid excreted was distinctly lessened, while afterwards it was increased. Drs. Putnam and Pfaff have failed to confirm this. The elimination of uric acid bears no relation to epileptic seizures. The uric acid doctrine dies hard, and its worshippers cling to it most faithfully. In Dr. Putnam's opinion, it is probable that too much weight has been thrown in recent years on the rôle of toxemias in the production of symptoms of disease.

Ascending Paralysis.—Dr. Charles G. Stockton of Buffalo reported a fatal case of this disease in a domestic servant of twenty-seven years. For some months before the development of severe symptoms there were noticed inexplicable nervous symptoms: pain, restlessness, sleeplessness, loss of weight (20 pounds), and weakness. Some improvement in the general symptoms and in weight occurred uring a month in the country. Later paresthesia developed, then anesthesia of the buttocks, followed by involuntary stools. The legs grew weak and at first painful, then senseless. Later the body and arms shared in the paralytic condition until finally the head alone had feeling and movement. The temperature had been regularly taken for months before, and was not abnormal. For several days before death it was 102° F. or above. An autopsy could not be obtained, but it was supposed to be a case of acute ascending myelitis. For some weeks before the end the urine was of a claret color. Chemical analysis showed the coloring matter present to be hemato-porphyrin. Some trional was administered several weeks before death, but not enough to cause the appearance of hemato-porphyrin in the urine. Hemato-porphyrinuria has been reported in certain cases of post-diphtheritic palsy, and it is a question whether this symptom should not be looked for in other forms of acute paralyses.

Trional and Hemato-porphyrinuria.—Dr. Putnam of Boston said in the discussion that re-

cently he had a case very similar to that reported by Dr. Stockton. The same train of clinical nervous symptoms, beginning with impairment of sensation and culminating in total loss of motion was noted. The diagnosis lay between acute ascending paralysis, Landry's disease, and multiple neuritis. The same claret-colored urine noticed by Dr. Stockton was observed, and the color was found to be due to hemato-porphyrin in the urine. Some trional had been taken by this patient also. Though none of the drug was prescribed for two weeks before the fatal termination yet the hematoporphyrinuria continued. A most careful postmortem was made by Dr. Councilman, who reported the cord and brain to be absolutely unaffected, but a series of neuritic changes existed in many parts of the body.

Dr. Janeway said that he had under his care for the last year and a half a woman in whom a multiple neuritis of the most pronounced type developed. The greatest care had been taken to exclude all other forms of toxic neuritis, especially as regards alcohol and lead. The only conclusion possible, under the conditions, seemed to be that the active toxic agent in the affection was trional, which the woman had been taking for some time, in 20 to 25-grain doses for the relief of sleeplessness. The neuritis was of the severest type and the symptoms did not remit for months. It is only now, at the end of over a year, that her condition can be said to be notably improved.

Infant Immunity to Contagion.—Dr. A. C. Abbott of Philadelphia said it has long been said that very young children were but little liable to contagious disease, although exact statistics in support of the statement were not often quoted. From 23 to 32 per cent. of all children die under one year of age. Although many less die during other years, very much fewer die from contagious diseases during this first year. Of the infants who die from contagious diseases during the first year over 80 per cent. die during the last six months, and only 3 per cent. during the first three months. Now it is during the first three months that the infant mortality is highest from other causes. Some explanation is needed for this very striking immunity. Baumgarten has suggested that it is due to the fact that infantile tissues possess a resistive power for bacteria. This is, however, merely theory with nothing to substantiate it. It has also been suggested that children are more cared for at this earliest period. As a matter of fact, however, we know that the children of the poor are miserably neglected while young. Mothers, without any idea of sanitary precautions, nurse them and then confide them to the care of the little ones of the family for hours. The best explanation seems to be one derived from some recent observations of Ehrlich. He found that immunized animals did not confer immunity by direct heredity upon their offspring, but that as long as the young animals suckled they were protected from the disease to which their mother was immune by an immunizing principle, which is contained in the milk. These protective properties of the milk were amply demonstrated. Among human beings most women have had the ordinary contagious diseases and have acquired a lasting immunity. It is probable, then, that their milk contains an immunizing principle which protects the child from contagious diseases so long as it nurses.

In the discussion Dr. Trudeau said that Baumgarten's theory of the resistance of young tissues to bacteria certainly did not extend to animals. Young guinea-pigs can be infected very readily with any germ-disease.

Dr. George Shattuck of Boston said that diphtheria conferred no immunity, or at most a very temporary one, yet young children were also immune to this according to the statistics given. They were certainly not protected by any immunizing principle in the milk in the case of diphtheria, so that it seems to be evident that other factors besides protective milk play a rôle in making contagious diseases so very rare in the very young.

Recurrent Vomiting in Children.—Dr. J. P. Griffith of Philadelphia said that he has recently observed four patients with obstinate vomiting as their principal symptom, which seem to deserve special treatment. In severe cases the vomiting is so persistent and the constipation so obstinate that intestinal obstruction may be suspected. Death seemed imminent in two of his patients. Chloral and bromides were vomited. In one case the child lay helpless on its side for hours, with dark material, and sometimes blood, flowing from the mouth. It no longer had the strength to vomit. The child seemed too weak for morphine, but finally this was given hypodermically, and relief followed. In two other cases, however, morphine did not seem to give relief. In one case chronic appendicitis was suspected and an operation was performed. No other attack of vomiting occurred for eight months, and then a fatal attack developed. In none of the cases were there any kidney symptoms until the terminal stages, when albumin and casts were present in the urine, and in one case edema was noted. Leyden reported a series of cases of intermittent vomiting in adults, which came on without known cause. The attacks resembled the gastric crises of locomotor ataxia. Some neurologists claim that Leyden's cases were true gastric crises of latent tabes and one patient actually developed tabes later. In children, however, such attacks have been reported rarely. In Griffith's cases digestive disturbances and prodromes were absent. The attacks occurred at irregular intervals, from three weeks to sixteen months apart, and lasted from two to eight days. While death seemed inevitable, recovery occurred in two cases, and when the patients began to mend convalescence was rapid.

The attacks of intermittent vomiting seemed to be due to a neurosis on a toxic basis, emesis being the result of the effort by the gastric mucous membrane to eliminate the toxic material.

Character of Vomit.—Dr. Stockton said that a

word should be added about the character of the material vomited. Examination shows that it is practically pure gastric juice according to all the chemical tests. There is an excess of hydrochloric acid, and as soon as that disappears convalescence begins. A certain periodicity of the disease may be noted even in children. Dr. Stockton has never seen a death from the disease, though at times it has seemed impossible that the child should continue to live. Death must be due to some complication in an important organ besides the stomach.

Dr. Johnson of Washington said that in children intermittent vomiting always occurred in the offspring of neurotic parents. Usually the children were precocious, at times neurasthenic, often hysterical. Just when death seemed certain recovery came. At times the vomit contained blood, fresh, or more usually altered, so-called coffee-ground material. The symptoms of prostration were often intense. The extremities and tip of the nose became cold and cyanotic, the lips blue, the child became restless in its exhaustion. This choleraic condition seems to be due to the abstraction of water from the tissue by vomiting and can be relieved by the hypodermatic injection of normal salt solution. By this means also the toxin in the circulation, which may be the same as in neurasthenia, is diluted.

Dr. Kinnicutt of New York said that enteroclysis is also of great benefit in this condition. The increase of blood pressure also causes a freer elimination by the kidneys. Dr. Forchheimer of Cincinnati said that milder cases of this cyclic vomiting, apparently without definite pathologic basis, occur. In the intervals the children are constipated and are always neurotic. The malady has been called a psychosis by certain German neurologists. Hysteria is more frequent in children than has been thought. There are certainly toxins in these cases that are being eliminated by the stomach. The treatment should be directed to the intervals of the attacks. The constipation should be relieved, the child not allowed to overwork intellectually, nor over exercise physically. The general health should be improved.

Sanitarium Treatment of Pulmonary Tuberculosis and Its Results.—Dr. E. L. Trudeau of Saranac Lake, N. Y., then read this paper, which will appear in a subsequent issue of the Medical News.

Tuberculin and Its Uses.—In the discussion Dr. Bridge of Los Angeles said that tuberculin, even when used as carefully as by Dr. Trudeau, seems to do very little, if any, good. In other hands it often does harm. The use of any serum for treatment seems to lead inevitably to a neglect of other and especially the precious hygienic, dietetic, and therapeutic measures. If but rational means be employed the successful treatment of consumption outside of sanatoria is very possible. Three-fourths of the cases of incipient tuberculosis either are unable or cannot be persuaded to go to a sanatorium. For these the open air treatment at home can accomplish great things. Too many physicians labor under the delusion that the open air treatment means exercise in the open air. They advise long walks, bicycle riding and the like, and work untold harm on feverish patients. Some physicians also foolishly counsel the avoidance of the night air, as if there were any harm in the air itself after sundown. Then patients are allowed to eat often and what they wish instead of being counselled to eat often and plentifully of the most nutritious diet. Eat consumptives must, *nolens volens*, and their digestion must be cared for for this purpose. Dr. Soloman Solis Cohen of Philadelphia asked if respiratory gymnastics were not good for the consumptive. He had found them so in practice. He asked if Dr. Trudeau did not favor them. As to the tuberculin test Dr. Cohen thinks that it has positive disadvantages while its advantages are dubious. It should be employed only by the most skilful. While in Dr. Trudeau's hands it has been useful and its employment is thoroughly justified, it has, undoubtedly, been a fruitful source of harm in the hands of the inconsiderate and inexperienced.

Early Diagnosis of Tuberculosis.—Dr. Trudeau in closing the discussion said that a most useful means of early diagnosis of tuberculosis, which is too often overlooked, is the regular taking of the temperature several times a day for a week or ten days. When any disturbance of health exists, and the evening temperature runs above 99½° F., there is almost surely tuberculosis present. It is surprising how many careful physicians neglect this simple means of very early diagnosis. As to the use of tuberculin it seems to be a valuable means of diagnosis, and we need further information with regard to it. One thing is certain, it should never be used when there is fever or when the case is progressive. Some experiments on animals at Saranac seem to prove that the injection of such doses of tuberculin as are used for diagnostic purposes do not do harm. Guinea-pigs inoculated with tuberculosis did not die sooner as the result of injection of tuberculin. A still more demonstrative experiment was made upon rabbits. Injections of tuberculous material were made into the cornea. Here the progress of the local tuberculous process can be watched very readily. Into some of the animals tuberculin sufficient to produce a reaction was injected. Others were left untreated. The progress of the tuberculous processes was the same in both classes of animals. This would seem to be a demonstration of the inocuousness of the tuberculin.

Patients suffering from tuberculosis need the care of a physician to supervise their exercise, diet and digestion. This they do not have continuously for months outside of a sanatorium, and, consequently, the open air treatment at home usually fails.

Oxaluria.—The secretary read, for Dr. C. A. Herter of New York an account of some work done in his laboratory by Dr. Helen Baldwin of

New York, on oxalates in the urine. Oxalate of lime is found in normal urine in varying quantities from traces up to 35 milligrams in the twenty-four hours. The average excretion of oxalates is about 10 milligrams a day. Most oxalates come from oxalates consumed, and exist quite plentifully in certain plants, as in rhubarb. There is only one condition in which the oxalates are produced within the body. This occurs in certain cases of fermentative dyspepsia. The withdrawing of a test meal, even where only proteids were given, has shown that oxalic acid can be formed *de novo* in these circumstances.

In the discussion Dr. James Tyson of Philadelphia said he does not think that oxalate of lime in the urine is ever of pathologic significance. It occurs irrelevantly in nervous and in perfectly healthy people. No connection can be traced between it and any symptom. It can be removed from the urine very readily by an absolute milk diet. Vegetables seem to favor its recurrence.

Acute Suppurative Gastritis.—Dr. Kinnicutt of New York presented the stomach of a patient dead from acute suppurative gastritis of the phlegmonous variety. The submucous gastric tissue was more than an inch thick near the pylorus. The tissues were all infiltrated with pus corpuscles. The only organism found in the stomach was a streptococcus growing in long chains eight to ten members in each chain. The patient was an alcoholic. The symptoms developed after a preliminary chilliness, not a chill, followed by fever with symptoms of pain. A state of collapse then developed. The affection was diagnosed peritonitis from perforation of a duodenal ulcer. He was considered too weak for operation.

Dr. Janeway said in discussion that in a similar case the diagnosis was perigastritis, cause unknown. These cases were extremely difficult of diagnosis.

Second Day—May 2d.

Actinomycosis Organism and Lesions.—Dr. J. H. Wright of Boston exhibited stereoscopic pictures of the ray fungus and its lesions. He said that the disease is commoner in the human being in this country than is usually thought. The lesions are small abscesses in a connective tissue capsule. Within these abscesses may be found the radiate filaments from which the disease derives its name. Between the filaments there is hyaline material which is really composed of dead filaments. Club-shaped characteristic appearances occur at the periphery of a colony. There are also degenerated filaments. When the disease becomes generalized, abscesses may occur in the kidney, lung, liver, the abdominal wall and in the extremities. Dr. Wright exhibited an abscess of the human heart wall bulging into the ventricle. The disease in this case began in one of the vertebræ and spread to the pleura.

Diagnosis.—The diagnosis of the disease can be made from certain granules that occur in the pus of the abscesses. They are gray in color, often of pearly lustre, of the size of a head of a pin or smaller. When the granules are crushed beneath a cover glass, they break up into segments that have, under a low power, a chrysanthemum appearance. This radiate structure is very characteristic, but to obtain it the granules must be perfectly fresh when crushed. The microscopical diagnosis depends on the presence of filaments which branch, this is essential, and in the midst of these there occur darker bodies, the so-called spore forms. In the discussion Dr. Da Costa of Philadelphia said that the most effective drug for the treatment of actinomycosis is potassium iodide in large doses. This has commended itself to the veterinarians and has in Dr. Da Costa's hands given very good results in human beings, especially at early stages of the disease. Properly used the remedy is permanently curative.

A New Pathogenic Fungus.—Dr. Hektoen of Chicago exhibited slides and photographs of a sporothrix resembling that first described by Schenck at Johns Hopkins. It was found in a boy in whom multiple abscesses occurred on the hand and arm, as many as twenty in all having been opened. In the thick, viscid pus from these abscesses, this sporothrix was found in pure culture. In stroke cultures it grows with radiate feathery margins. In plate cultures spore bearing threads occur at the periphery. Conidia or spores are noted all along the filaments but especially at the ends where five or six may be grouped together. There are distinct septa in the threads.

The organism is especially pathogenic for mice and white rats. It produces typical ulcers with undermined edges. On the peritoneum it produces tuberculiform nodules. The spores are club shape, not unlike those of actinomycosis. Only three cases of the disease have been reported in the human being, and one of these was recognized clinically but not studied bacteriologically. Infection took place in all three cases through a small wound of the hand. The cases occurred in widely separated parts of the country. It is probable then that the disease exists much more commonly than might be thought.

Pernicious Anemia.—Dr. Richard C. Cabot of Boston detailed some conclusions arrived at after a study of 110 cases of this rare disease. Although contrary to the usual experience there were more men than women among his cases. Only four of the cases followed parturition. Pernicious anemia is distinctly a disease of the age past forty. Eighty-two of his patients were over forty, nineteen over sixty, four over seventy, the oldest was seventy-nine, the youngest nine years of age. The fatal anemias in early childhood are not included in this list. The number shows that the disease is much more frequent near Boston than has been thought. The same probably holds true for the rest of the country. It is interesting to know what it is called when not recognized. In one case near Boston it was diag-

nosed general tuberculosis, by which was meant supposedly acute miliary tuberculosis. In three cases because of the presence of fever it was thought to be a typical protracted typhoid fever.

Etiology.—This is difficult to trace. Fourteen cases occurred about the time of the menopause, but could not be said to be connected with it. Four cases had tertian malaria, but this does not seem a causal factor despite all that has been said on the subject. Only one patient gave a history of syphilis. Thirty-seven had suffered from hemorrhage but this seemed to be a symptom, not a cause. The favorite sites of bleeding in the order of frequency were the bowels, nose, and gums. In one case a hemorrhage of over a pint took place from the external meatus of the ear—an unusual location for the source of bleeding in so large a quantity.

The disease is never constantly progressive. A number of the cases felt tolerably well and were even able to work at intervals. There is no constant relation between the symptoms and the extent of the anemia. One man with but one-half million of red blood cells wanted to go to work; another with a blood count of three millions felt incapacitated. There is some other factor besides anemia, probably a toxemia, that influences the symptoms. The first symptom in every case is intense muscular weakness. Dyspnea is another universal symptom. Gastro-intestinal symptoms are common, but they are neither constant nor progressive. Intervals of perfect digestion occur. This would not be true if the disease were due as some claim to atrophy of the gastric tubules. The appetite is capricious, often poor. In two cases appetites were too great to be satisfied. Fever is noted two-thirds of the time. In two cases the dark urine so often spoken of was present. In the other cases pale urine was excreted. In one-third of the cases nerve symptoms developed. These are due to changes in the spinal cord and may simulate tabes or diffuse myelitis. There is always a marked leucopenia. In one case less than 1000 white cells to the cubic millimetre were present. Megaloblasts were found in every case where more than one blood examination was made.

Remissions — Causes — Significance. — Pernicious anemia is never progressive, despite the use of that word in its usual name. The causes of the remissions are unknown. They are usually attributed to some treatment that is being administered at the time. Nothing seems capable, however, of modifying the progress of the disease, which is very capricious. During a remission the number of red corpuscles increases. Sometimes the hemoglobin does not increase as fast and a disproportion between corpuscles and coloring matter occurs which gives the blood picture of chlorosis, that is of secondary anemia. It is well then to know the history of the case before venturing a diagnosis. When the red corpuscles increase in number the leucocytes do so also. This gives rise at times to a leucocytosis—a rare event. During remissions the red cells are often very large. In one case with 2,500,000 reds the patient was healthy and ruddy. His red blood cells contained double the normal amount of hemolobin, so that with only 50 per cent. of cells he had 100 per cent. of hemoglobin. In this case the red cells were so large that they resembled the blood corpuscles of some other species of animal. After some time of remission this case relapsed to a fatal termination.

Differential Diagnosis.—It is not so difficult as is often claimed to differentiate primary or pernicious from secondary anemia. The differential diagnostic points are, briefly, as follows: Pernicious anemia develops slowly, is painless and insidious, the patient's appearance of good health remains for a long time, symptoms referable to the spinal cord develop very frequently, there are paroxysmal attacks of gastric disturbance and there are marked remissions in symptoms which bear no relation to treatment. In secondary anemia a cause can be found; there is a steady progression as long as that cause acts; there are many small red corpuscles present; megaloblasts are much less numerous than in pernicious anemia and there is a disproportionate reduction in the hemoglobin.

Course of Pernicious Anemia.—The average duration of the disease is from one to two years. It may last with remissions for five years. Coma may develop, and yet the prognosis of approaching death is not justified. Dr. Cabot has had a patient recover from pernicious anemic coma to comparative good health. No patient in whom the diagnosis of the disease seemed justified has ever recovered.

Treatment.—No method of treatment seems to have any effect on the disease. Arsenic is useless, bone-marrow futile. Only laxatives seem to do any good. This would seem to confirm the theory that the disease is due to an intoxication and that some of the toxins may be eliminated by the intestinal mucous membrane. All the mild cases of the disease have diarrhea, and this also supports the theory mentioned.

Symptoms of Pernicious Anemia.—Dr. Frank Billings of Chicago discussed nineteen cases of pernicious anemia. Eleven were males, eight females. The average age was forty-six years. The average age in Byron Bramwell's cases was forty-five years—a practical agreement of statistics. In none of the cases was there any known cause for the anemia. In but one case had there been syphilis. There was not alcoholism, nervous shock, mental worry, nor overwork, physical or mental. The first and invariable symptom was the intense muscular weakness. This was practically always accompanied by dyspnea and palpitation of the heart. Diarrhea, as in Dr. Cabot's cases, was the rule. Nervous symptoms developed in one-third of the cases, and the first symptom was usually paresthesia of the legs. Headache was common: sleeplessness and restlessness frequent. It one case the first symptoms noted were due to the changes in the spinal cord.

The condition was diagnosed myelitis by one neurologist and neuritis by another. Paraplegia developed and the blood showed the characteristic picture of pernicious malaria. A very common symptom is the lemon-yellow color.

Blood Findings.—The number of red blood cells is sometimes very much reduced. In one case there were less than 200,000 to the cubic millimetre. The nucleated red corpuscles are not only of diagnostic but of prognostic importance. They usually become much more numerous shortly before death. On the other hand, just before a decided remission sets in there is a crisis in the nucleated red cells and they may even entirely disappear. This does not mean lasting cure, however. Relapses always occur. There are, perhaps, possibilities of cure in pernicious anemia, but there are no cases recorded, and the more the disease is studied, the more absolutely hopeless it seems.

Clinical Notes on Pernicious Anemia.—Dr. Frederick P. Henry of Philadelphia said that either pernicious anemia is not so frequent in Philadelphia as in Boston or else it goes unrecognized. He has not seen anything like the number of cases reported by Dr. Cabot, though he has been faithfully studying the disease since 1878. Five recent cases seem worth reporting for various reasons. One of the patients felt in very good health, with but 2,500,000 of red blood cells. It is probable in this case that the number of red cells natural to the individual was low and that 50 per cent. of the normal number was not so far away from the healthy condition as might be imagined. In one case a patient, discouraged by bad reports from the blood counts, refused to allow any more, though he adopted all measures of treatment advised. In one case Breckinridge's transfusion method was employed. Human blood was used for the purpose. It was kept fluid by the addition of 5 per cent. solution of phosphate of soda. Six ounces of blood were obtained from a negro who suffered from epilepsy. Ten days after the transfusion the pernicious anemia patient developed a conclusive attack, with spasms limited to the right side of the body. As he had never suffered from any convulsive seizures before, this occurrence created a great deal of comment because of the transfusion of blood from an epileptic. No improvement of the pernicious anemia followed the transfusion and further convulsions did not occur.

Treatment and Possibility of Cure.—There are certainly remedies that benefit the disease. Among these in the first place is arsenic, pushed to its physiological limit. In one case Dr. Henry has seen an absolute cure. The remedies employed were naphthalin, as an intestinal antiseptic, until it became too unpleasant to take from its persistent after taste. After this bismuth salicylate was employed and frequent minute doses of calomel. The appetite was practically nil and seemed to be greatly benefited by orexin. This did not prove similarly effective in other cases of the disease with this symptom of lack of appetite.

Special Peculiarities.—In two cases freckle-like spots developed on patients suffering from pernicious anemia. In one case this was accompanied by a universal bronzing. The disease has a tendency to be complicated by erysipelas and one of Dr. Henry's cases died from that affection. The diagnosis of secondary anemia due to gastric cancer is not difficult as the number of red blood cells is never as much reduced as it is in pernicious anemia. Dr. Henry has not seen less than 1,000,000 red blood cells in cancer cases.

Family Pernicious Anemia.—Dr. Kinnicutt of New York reported a fatal case of pernicious anemia in a child of seven years. The special interest of the case attaches to the fact that the sisters of the child, aged respectively fourteen and sixteen years also suffered from pernicious anemia although neither of them has died as yet.

Dr. Hobart Amory Hare said in discussion that pernicious anemia cases come oftener from the country than from the city. At Jefferson Hospital they come especially from the mining regions of Pennsylvania. Certainly the transfusion of blood cannot do any good in these cases since we know that the blood corpuscles of one animal will not live in another animal nor even those of one human being in another. Most of the benefit derived from such treatment is a mere coincidence.

Oral Suppuration.—Dr. Wm. H. Thomson of New York said that Hunter in his last 10 cases reports that in all of them there were suppurative processes in the gums and at the roots of the teeth. When the stomach was washed out it contained a notable number of streptococci. In the last case of pernicious anemia that came under Dr. Thomson's care the patient's mouth was carefully examined. No less than eight carious teeth were found and one tooth was pouring out pus. Hunter's theory is that in these cases the constant swallowing of purulent material leads to the production of a toxemia and in addition the presence of large numbers of micro-organisms of suppuration in the stomach disturbs digestion and nutrition. This idea of Hunter that the condition of the oral cavity may be an etiologic factor in the disease deserves further investigation.

Hypodermoclysis for Pernicious Anemia.—Dr. McPhredran of Toronto said that of 22 patients with pernicious anemia that he has seen 2 have recovered. He has used hypodermic injections of various sera, diphtheria serum when no other was at hand, and normal salt solution at times and has had excellent results in relieving severe symptoms. The average duration of weakness, tendency to coma and the like Dr. McPhedran thinks is larger than was said by the readers of the papers.

Dr. S. Weir Mitchell of Philadelphia said that all blood counts were relative, not absolute. Some years ago Dr. John K. Mitchell showed how much difference in successive blood counts was made by massage in the interval. Wherever the circu-

latory blood can be seen it will be noticed that clumps of cells remain for some time stationary at the divisions of blood vessels, and in small loops of the capillary circulation. These are turned into the circulation again by massage.

Dr. Stockton said that careful examination of the stomach contents of patients suffering from pernicious anemia showed that hydrochloric acid was absent in all cases. Before the fatal termination all digestive power ceased entirely and the condition known as achylia gastrica developed. This seemed to confirm the theory of the etiological importance of atrophy of the gastric tubules.

Dr. J. C. Da Costa of Philadelphia said that as to the length of remissions it did not seem to be affected much by conditions. In a clubman who was not a man of excesses but absolutely indolent the remission lasted eleven months; in a sailor who worked hard in the interval the remission lasted seven months. Dr. Da Costa has often seen high fever accompanying pernicious anemia and has even seen the disease mistaken for typhoid fever.

In closing the discussion Dr. Cabot said that on patients suffering from pernicious anemia massage has less influence in causing variations in the blood counts than it has in healthy people. This he knows by actual experiment. As to transfusion it is not only useless but dangerous. Franz Pfaff has shown recently that blood injections are especially liable to damage the kidneys.

Proliferation and Phagocytosis.—Dr. F. B. Mallory of Boston read a paper in which he showed that weak toxins in the circulation cause cells to take on proliferative conditions, while stronger toxins cause necrosis and exudation. He showed that phagocytosis, in addition to being protective, as in the destruction of bacteria, may be malignant when body cells consume others. He described the state of affairs in an active testicle removed from an old man of seventy years of age to relieve hypertrophy of the prostate. In the epididymus large phagocytes could be seen swallowing active spermatozoa.

The Strongylus Intestinalis.—Dr. W. S. Thayer of Johns Hopkins showed pictures of this rare parasite which was obtained from the stools of a young man who was never out of this country, spending most of his life at Richmond, Va. This is the second time this parasite has been seen in this country. The other case was a native of Austria. It is probable that the worm is commoner than is supposed. It is usually associated with the anchylostoma duodenale and when one is found the other should be sought. Whether the parasite causes diarrhea or not is a question. When first seen in cases from Cochin, China, and the St. Gotthard's tunnel, it seemed surely pathological, but this is now doubted. The question is worthy of further investigation.

(To be Continued.)

The State Forests Increased.—The New York State Forest Preserve Board has decided to purchase a tract of 300 acres of forest land.

AMERICAN PEDIATRIC SOCIETY.

Twelfth Annual Meeting, Held at Washington, D. C., May 1, 2, and 3, 1900.

First Day—May 1st.

President's Address.—Dr. Henry Koplik, of New York, read the annual address, entitled "The Ambulatory and Hospital Management of the Gastro-Intestinal Derangements of Infancy During the Summer Months among the Poor of Large Cities." He held that the breast-fed infant is not exposed to as great or as many sources of infection as the artificially-fed infant. In the latter, cow's milk is the substitute for the breast by common consent of all practical men. Yet before it reaches the infant, it passes through so many channels and is exposed to so many chances of infection that the wonder is the mortality is not larger than it really is. Milk, above all articles of diet, attracts to itself infection, even if such infection is not directly introduced into the milk. The animals from whom the milk is obtained can first introduce infection, and in saying this Dr. Koplik did not refer to tuberculosis, but to filth. The udder of the animal may be the means of introducing into the milk streptococci, which can cause virulent forms of diarrhea. Dairy dirt also may be introduced into the milk during milking. Again, in passing from utensil to utensil in commerce, the milk is exposed to a thousand and one sources of infection. Practical men will agree that cleanliness is the light that has penetrated the dark and baffling problem of infant-feeding. The foundation of all artificial feeding must necessarily be the breast-feeding; and yet, in this natural method, the greatest diversity is found in the quantity and quality of the food, tending to give equally brilliant results. In a limited number of studies on breast-fed infants, the result tends to show that the quantities vary; that one infant will take eighty-nine caloric equivalents daily, while another will take 126 caloric equivalents, and yet both infants will be equally well nourished. The fat varies largely in the same milk and in the milk of various breasts, and yet the children of each breast thrive. In cow's milk, the problem is a more difficult one. The milk must not only be diluted, but the waste of the proteid constituents of the milk is large even in thriving infants. The increase in the phosphorus in the excreta indicates this. It is not sufficient, therefore, to simply construct the infant's milk of the breast proportions, but the waste and the necessity of dilution must be taken into account. The keynote of Dr. Koplik's theme was that the gastro-intestinal diseases, both mild and severe, are, in the vast number of cases, infectious.

Intestinal Obstruction.—Dr. Irving M. Snow of Buffalo, N. Y., presented a specimen in which Meckel's diverticulum measured twelve inches, the portion constricted being the last foot of the ileum. The patient was a boy, three years of age,

and in good health up to the present illness. The history of the case is that he fell a short distance from some steps, striking on the abdomen to the right of the navel. Not any bad effects followed this accident; in fact, there was complete relief in an hour. A day or so later the child ate freely of grapes, and there was reason to believe that this dietetic indiscretion, by producing intestinal irritation and increased peristalsis, was the exciting cause of the obstruction. Three days after the accident the boy had a normal fecal passage, but commenced vomiting and vomited persistently for four days. Laxatives and enemata failed to move the bowels, which were obstinately constipated during five days. There was also agonizing and nearly continuous abdominal pain so intense as to require opiates. There was not any tenderness, induration or abdominal tumor to be felt. The belly was slightly distended and there was some gurgling and rumbling on palpation. The temperature was slightly above normal, and, as a matter of fact, the illness ran its entire course without fever. After an illness of twelve days the patient died. The post-mortem showed that the cause of death was due to exhaustion and inanition from pain, vomiting, and interruption of assimilation from an unrecognized abdominal obstruction. The condition was not recognized as intestinal obstruction, and not being relieved by operative treatment ended in death.

Dr. Augustus Caillé of New York reported a case in which the symptoms of obstruction were present, but the obstruction was not complete. It was his conclusion that in such instances exploratory laparotomy should be done on the first occasion of fecal vomiting. The case reported resulted in death, but the patient might have been saved by prompt surgical interference, as suggested.

Dr. Samuel S. Adams of Washington reported a case that was not operated on until the symptoms became alarming. While the patient was being placed under anesthesia there was a free movement of the bowels, but on opening the abdomen the invagination was found to be undisturbed. The patient recovered.

Dr. W. S. Christopher referred to a case where air was injected into the intestines after the abdomen was opened, and it was his opinion that sufficient pressure could have been exerted to burst the intestines without loosening the intussusception. This case was of especial interest inasmuch as it was the second time intussusception had occurred in the same patient and been treated by Dr. Christopher. The patient recovered from the second attack.

In closing the discussion Dr. Snow said it was extremely difficult to make a diagnosis in cases where the symptoms are obscure. It was his opinion that an exploratory incision should be made if there be even a doubt as to the diagnosis.

Pancreatic Digestion of Caseine.—In the experiments set forth in this paper Dr. B. K. Rachford of Cincinnati, O., used rabbits' pancreatic juice, which was collected in a common receptacle and afterward equally divided between the digestion tubes of an experiment, so that each tube might contain an equal quantity of pancreatic juice of like digestive capacity. The bile was also obtained from the rabbit, and filtered before using. Ordinary dairy milk was employed which had been boiled and neutralized. He observed at the close of certain experiments that free fat or butter was found floating on the surface of digestive mixtures in which the milk had been subjected to the action of both bile and pancreatic juice. The physiological emulsion of fats, as it occurs in milk, was partially destroyed by the combined action of bile and pancreatic juice, but this emulsion was not destroyed by either one of these agents when acting alone. This led to the observation that possibly the emulsion of fats in milk is wholly or partially destroyed by the action of bile and pancreatic juice in the intestinal canal prior to their absorption.

Dr. Augustus Caillé, in discussion, approved of hydrochloric acid to assist digestion in children from one to two years of age.

Dr. L. E Holt of New York said he did not believe in giving hydrochloric acid to babies. He thought the best way was to pay attention exclusively to the diet.

Dr. A. D. Blackader agreed with Dr. Holt that the diet was of paramount importance.

Dr. T. M. Rotch of Boston did not think that farinaceous matter assisted digestion as much as lime-water, and, therefore, there might be some objection to the former. He preferred giving lime-water.

Dr. Rachford, in closing the discussion, said that his paper was not intended for a clinical paper. His object was to determine how babies should be treated; how these investigations are to be followed would have to be determined afterward. There were two things to be considered, he said. One was whether hydrochloric acid did cause a larger amount of caseine to be digested by the pancreatic juice, and the other was whether in examining the stomach hydrochloric acid was found to be deficient.

Operative Treatment of Tuberculous Peritonitis.—Dr. Augustus Caillé presented this paper and stated that the cases related were carefully studied by him before operation and had been under observation for two or three years after operation, so that he had a clear insight as far as the beneficial effects of the operation were concerned. A number of cases were reported, including one in which a diagnosis of tuberculous peritonitis was made by exclusion and in which tuberculosis of the hernial sac was discovered during a Bassini operation for the cure of the hernia, which operation also affected a cure of the tuberculous peritonitis, although the abdomen was not encroached upon.

Another interesting group of cases presented solid tuberculous tumors of the peritoneum and mesentery, two of which Dr. Caillé had observed himself. They presented a distinct variety apart

from the other well-known forms of tuberculous peritonitis. A particularly interesting case was one in which the diagnosis was made quite early, but operative interference was refused, and for the greater part of two years all known methods of medication, internal and external, were persisted in without any apparent benefit.

From a study of the cases presented, Dr. Caillé's conclusion was that medication is futile as far as cure is concerned. The diagnosis is made by exclusion, except where the tubercle bacillus is found in the puncture fluids, when a diagnosis is positive. In all doubtful cases an exploratory laparotomy is imperatively indicated because surgical interference can only effect a cure in cases that are recognized very early and are not complicated by tuberculosis of other parts. The main diagnostic features are the abdominal symptoms, pain, distention, disturbed bowel action, effusion, and in every case carefully observed by Dr. Caillé there was a low, irregular tumor. It was not characteristic in itself, but was present in every case observed.

Dr. J. Henry Fruitnight of New York said he had obtained good results in the Children's Hospital following an operation in a number of cases of tuberculous peritonitis, but he did not believe that the recovery in such cases could be considered permanent.

Dr. Rotch, referring to some two hundred autopsies in fatal cases of diphtheria in infants and young children, in which there were seventeen cases of tuberculosis in some part of the body, emphasized the importance of diagnosis between primary and secondary peritonitis. The treatment of tuberculous peritonitis, which is secondary to disease of the lungs, is almost useless. When the disease is primary, laparotomy gives good results. He stated that many cases of peritonitis, with or without effusion, are tuberculous even when the tuberculosis may not be demonstrated. He reported a case in which an enlarged mesenteric gland was removed, and dwelt on the importance of the early removal of such glands whenever they are tuberculous, in order to prevent the further spread of infection. The use of tuberculin in diagnosis was considered by him very important, especially in cases where there is a low range of temperature, because where the temperature is 102° or 103° F. the result is not so favorable for its use.

Dr. A. C. Cotton of Chicago stated that in the absence of positive clinical evidence he was often driven to bacteriologic findings to decide the diagnosis in suspicious cases of tuberculous peritonitis. He raised the question as to how far practitioners are justified in doing exploratory laparotomy in such cases.

Dr. Rotch replied that he did not see why exploratory laparotomy should not be done in all cases.

Dr. Jackson laid stress on the examination of the blood for leucocytosis, although such examination would not differentiate the disease from typhoid fever.

Dr. Koplik called attention to sarcoma, which it is important to differentiate from tuberculous masses in cases of peritonitis.

Dr. Caillé, in closing the discussion, considered medicinal treatment in these cases of no avail, and stated that it was not worth while to waste time on guaiacol and creosote. The diagnosis, he said, is frequently not made positively because tuberculosis cannot be found. If the disease is suspected, then it is an absolute duty to open the abdomen. Fluid in the abdomen may be due to a chronic malarial infection or a large spleen or sarcosis, anemia, nephritis, or to valvular disease of the heart. It was his opinion that if the diagnosis could not be made otherwise the opening of the abdomen is harmless. The patient, being under an anesthetic, does not suffer pain, and it was Dr. Caillé's belief that a physician would be derelict in duty if he did not advise laparotomy in suspected cases in which the diagnosis is not absolute. He did not lay very much stress on the examination of the blood, as such an examination would not differentiate cases of tuberculous peritonitis, and every case of infection caused by chronic malaria or anemia, although he admitted that such an examination might sometimes aid in the diagnosis.

Studies on the Blood in Childhood.——In the absence of Dr. Alfred Stengel and Dr. C. Y. White of Philadelphia their joint paper on the above subject was read by title.

Second Day—May 2d.

The Treatment of Hydrocephalus by Craniectomy.—Dr. Edward P. Davis of Philadelphia, in his paper on the above subject, referred to the case of an infant six months old. The mother of this infant had two other children. Before the birth of this child the mother was in excellent health. The birth was spontaneous. The mother nursed the child for three weeks, when she had what was described as a "bilious attack," and the secretion of milk failed. The child was then fed on starchy food. The child weighed at birth five and one-half pounds, and at six months nine pounds. It was brought for treatment because it was restless and had a poor appetite and did not seem to be gaining. It was decidedly stupid and evidently suffered from intra-cranial pressure. The child was transferred to the Jefferson Hospital, where it was seen by Dr. W. W. Keen in consultation. An effort was made to secure continuous drainage, but it did not seem to withdraw the fluid from the ventricles. The child was anesthetized and under antiseptic precautions the cranium was trephined at one side of a sagittal suture and in the parietal bone on the right side. Dr. Davis thoroughly described the subsequent operations and results and stated that the child finally collapsed and died.

Dr. Rotch, in discussion, referred to a case in the Infants' Hospital in Boston, and said that so far as the operation is concerned, it seems to be very simple and no bad results come from the

operation as such. They were either treated with one tapping or, as in some other cases, they were kept for perhaps weeks with frequent drainage with tubes introduced into the ventricle, and the fluid withdrawn every day. The results were invariably bad so that the opinion in Boston now is, from what has been observed, that the operation is in no way curative. It may perhaps be palliative, making the child more comfortable for the time being.

Dr. Dorning reported a case where two ounces of fluid was withdrawn; after the puncture the child became very quiet, convulsions ceased and the child seemed to improve for about three weeks, but after that, unfortunately, he lost track of the case.

Dr. Koplik reported three interesting cases that came under his observation. In one case which he had seen lately, a baby, seven months old, developed symptoms very much like those in tuberculous syphilis. The child was tapped in the lumbar space and each time ten to twenty c.c., varying according to the indications, was taken. The baby seemed to improve after each tapping, the convulsions ceasing. After tapping the child six or seven times during the week, the results appeared to be good. By tapping the amount of fluid in the ventricle was reduced; it was not intended to take off all at once. The relief by pressure probably precipitated the result. It was a straightforward clinical case of chronic hydrocephalus.

Dr. Rotch stated that in a case he had operated on in the Infants' Hospital, the greatest care was taken to keep a record of the amount of pressure under which the fluid was withdrawn and the amount during the whole sickness until the child died. It was quite an interesting experiment but he did not think it would lead to anything clinically. It impressed him as being a palliative treatment.

Dr. Davis, in closing the discussion, said that the danger of immediate death seemed to depend very largely in this case upon the amount of fluid withdrawn, and hence the operator should be solicitous as to the minimum of fluid which should escape. Hence, the effort to maintain pressure while the drainage is being inserted.

The Nephritis of Influenza in Children.—Dr. Rowland G. Freeman of New York in presenting his paper, cited a case of a boy, four years of age, who, for the past three years, suffered each winter from an attack of influenza. The present attack began the first of January, 1899, with the ordinary symptoms of cold—prostration, fever, and moderate earache, but at no time was there any discharge from the ear. January 31st he had a temperature of 102.5° F., the highest temperature being 105° F. on February 5th. The temperature gradually diminished. February 9th it varied between 100° F. and 101° F. On this date the child passed some very red urine, which contained a considerable amount of blood, about 5 per cent. by bulk. His conclusions were that, although albumin is fairly frequent, the influenza of nephritis is a rare complication. The nephritis complicated in influenza is usually clinical, of an acute hemorrhagic type, and morphologically shows toxin lesions. It apparently attacks children more often than adults. Any disturbance may appear a few days after the acute symptoms of influenza or as long as a month later. He added that the prognosis is fairly good.

Dr. Fruitnight said, in discussion, that in fifty-seven cases he had found but one case of albumin which disappeared in a few days. It was a very rare complication.

Dr. Dorning thought more care should be exercised in examining children. He reported three cases of complicated nephritis. The entire family had suffered from influenza and no attention was given to the urine until one child, nine years of age, had shown some edema of the face. An examination of the urine showed 30 per cent. of albumin and a large number of blood-casts. This ran for three weeks before the casts in the albumin entirely disappeared. Another child, four years old, showed edema of the face. In this child's urine blood-casts were found. These conditions cleared up and the children recovered. Another case of a child, four years old, was reported in which influenza affected every member of the family, and showed a very pronounced form of nephritis. The mother brought the child to the speaker's office, stating that his face had become swollen and that the swelling had disappeared some four days previously. On examination the urine showed blood-casts and 50 per cent. of albumin. There was a loss of appetite. The urine is not yet cleared up, but the edema disappeared in three weeks.

Dr. Jennings reported one case of nephritis following a double infection. The influenza appeared first and was followed by nephritis. So far as his observation goes nephritis is equally as rare as a complication of measles. This case of nephritis was of a mild character. The urinary findings amounted to sixteen ounces, and the specific gravity 1015. There was an abundant precipitation of albumin, and also blood-casts. The urine cleared up in a very short time and the blood-casts disappeared on the third day. The granular casts persisted in a few numbers for perhaps a week. The urine increased to twenty ounces on the third day; twenty-eight on the fifth day, and after that the child was practically convalescent.

Dr. Rotch said it would be very interesting to see a post-mortem of a case following influenza. The probability is that these cases of nephritis and influenza are of an acute interstitial type following the general rule of an infectious disease. It is important to make a diagnosis of any special form of renal disease in young children by means of an examination of the urine; that is, if the rule is followed which is usual in making a diagnosis in adult cases.

Dr. Carr said that the clinical phenomena are very much the same as those reported by Dr. Freeman—temperature-range and other condi-

tions. In a case reported by him a very striking feature was the suddenly developed taste of the child for sugar. It would not take any medicine unless it was sweetened. The case was of interest to him because of a sudden increase in the specific gravity, this fondness of this child for sugar, and the absence of albumin.

Dr. Churchill said he would like to raise a question in these cases of influenza, and also other infectious diseases, whether they are not often the beginning of inward trouble which develop later on in life, particularly at puberty or still later, and whether we do not find manifestations of inward trouble by careful and thorough examination of the urine. Evidence was found of what might be called renal irritation after the actual nephritis. He reported a case of a young man nineteen years of age, suffering from an attack of appendicitis. He examined the urine simply as a routine practice and found chronic nephritis. It is his opinion that there is no way of determining the standpoint of the nephritis.

Dr. Caillé was astonished at the recuperative power in children. He has seen many desperate cases of nephritis cleared up in time completely.

Dr. Freeman, in closing the discussion, stated that the examination of this child's kidneys had been made more than a year ago, and during all this time the kidneys remained perfectly healthy, and he never had any deviation from the normal. Concerning the ear as a factor in this matter, there was at no time any otitis. During the month of January and the month preceding this attack the child complained at times of pain in his ear, but it passed off in a few hours, and there would be nothing more of it, perhaps, for a week. There was never any special tenderness about the ear, except for an hour or two. These cases are the result of a fairly exhaustive search through the literature of the past ten years, and he hoped by calling attention to this matter that there might be some interesting points made.

Bursting of Caseous Gland into the Trachea.—Dr. Augustus Caillé of New York presented a specimen taken from the body of a girl. The autopsy revealed a cold abscess about the size of a walnut, a little above the bifurcation of the trachea. The contents were cheesy matter. It had ruptured into the trachea and the cheesy matter from the abscess had completely flooded the trachea.

In response to inquiries, Dr. Caillé said that the child had been sent into the hospital with a diagnosis of bronchitis. The house-physician, in going over the child, heard a few râles beneath the sternum. The patient had no fever, no pain, and hardly any cough, but was playful and in apparently good health and was not put to bed at all.

Dr. Rotch, in discussion, called attention to the fact that many children are tubercular when there is no suspicion that tuberculosis existed. It was his opinion that in almost every case when a child has a cough, his health must be guarded. The case in question showed no evidence of tuberculosis.

Dr. Dorning stated that he had resorted in a great many cases to elevating the face, which tended to draw the trachea upward. And in only one case was he able to get a murmur. He was unable to say whether there was a large gland there or not, as the case passed from his observation and had no value from that standpoint.

Dr. Miller said that he had tried in a large number of cases the experiment referred to by Dr. Dorning, and it seemed to him that the murmur produced by tossing the head back and putting the face on a level plane is present in many normal cases.

Dr. West reported a case where the symptoms spoken of by Dr. Dorning were very prominent. He also referred to other cases where the symptoms were very prominent, and in one case that he had attended, the symptoms disappeared and then reappeared. In the case he saw last winter the child had a cough that resembled, to some extent, whooping-cough, and in another case he cited there was also resemblance to whooping-cough.

Endocarditis and Anuria.—Dr. A. C. Cotton, of Chicago, reported the case of a baby born March 19, 1900. The family history was negative, there being no history of syphilis obtainable. The mother was a primipara and had been well during gestation. She had never suffered from rheumatism. Labor normal. It was a well-developed child, presenting no external malformations. Meconium was passed shortly after birth. The child had a marked pallor which persisted, changing to a greenish hue, actual cyanosis supervening gradually. Examination of the heart showed a loud, harsh, diastolic murmur. It was heard all over the chest. It was hard to locate the exact position of this murmur. The child died of progressive asthenia on the fifth day, no urine having been secreted.

Dr. Samuel S. Adams, in discussion, stated that the question of anuria—the relation between the cardiac lesion as described and the anuria—does not mean that one is responsible for the other.

Enteric Fever in Childhood.—Dr. A. D. Blackader of Montreal in presenting his paper, referred to the outbreak of typhoid fever in Montreal which was due, in two instances, to the infection being conveyed in milk. He had made notes of twenty-nine cases of typhoid fever in his own practice, and had examined the records of forty-eight cases in the Montreal General Hospital and twenty-three cases admitted into the Royal Victoria Hospital. He treated of all the characteristics of the disease as manifested in these cases with the relative frequency of the various symptoms and the results obtained by treatment. His conclusions were the efficacy of the cold baths and the Brand method in the treatment of typhoid fever in children, and laid stress on the great value of the regular and systematic employment of the cool or cold bath in the treatment of this affection. It might be employed regularly without too rigid adherence to the rule of Brand of only using it when the fever reaches 102.2° F.

He pointed out that the baths are not to be employed for its effect on the temperature so much as for its effect on the nervous system and through it, on the heart, respiration and secretion—especially secretion from the kidneys.

Dr. A. C. Cotton, in discussion, said that the matter of interest to him was to note the effect of the free movement of the bowels against constipation.

Dr. W. P. Northrup was of the opinion that children under two years of age are little susceptible to the invasion of typhoid fever. He reported the case of a child 9 months of age, which was the sixth case of typhoid fever in the same family. This infant was put to bed with a typhoid patient, the mother being the only well one to take care of the family. He cited another case of a child thirteen months old who was fed by its father from the same cup he used himself. He said that one of his patients craved ice cream and when it was ordered, he found it to be largely composed of corn-starch.

Dr. Griffith stated that typhoid fever is a frequent occurrence in infancy under the age of one or two years, and the symptoms were difficult to recognize on account of the youth of the patient. He thought rose spots should be looked after more carefully. He referred to the numerous cases of typhoid fever in Philadelphia, where he had considerable experience both in hospital and outside practice. He stated that he had repeatedly given up first tubbing and then sponging, as he found the children grew blue and that the pulse became weak, and that the tendency was to make them worse instead of better. Children do not bear water as well as adults.

Dr. Rotch stated that the symptoms of typhoid fever do not appear in early life so well as in later years. He thought that the cases indicated by Dr. Northrup showed severe symptoms. They were not common symptoms. Out of hundreds of cases in the Children's Hospital, only the very severe ones die; as a rule, they are exceedingly mild in early childhood. The lesions are not pronounced at the autopsy. The rose spots, he thought, would be found more common than usually supposed.

Dr. Wilson said that he entirely concurred in what Dr. Northrup had said with regard to infancy, carrying with it up to a period of two years a certain degree of immunity as compared with the next period from two to ten years and ten to fifteen years—the degree of immunity as compared with adult life.

Dr. Dorning said that in the use of water he thought there was room for great discernment. He is impressed with hydrotherapy and its value and also with its potency for harm. To get the benefit of both it is necessary to get reaction. If the flush becomes blue, it is doing harm. He did not believe that babies stand tubbing well. He said a baby could not be put into a bath of 68° F. with a temperature of 105.

Dr. Northrup referred to two thousand autopsies on children under two years of age, and in none had he seen typhoid fever. Eleven hundred of these children were fed on "corner-grocery" milk. He does not believe a child one or two years of age is susceptible to typhoid fever but he thinks that if they do get typhoid fever, they declare it.

(To be Continued.)

AMERICAN GYNECOLOGICAL SOCIETY.

Twenty-fifth Annual Meeting, Held at Washington, D. C., May 1, 2 and 3, 1900.

First Day—May 1st.

The twenty-fifth annual meeting of the American Gynecological Society was called to order by the President, Dr. George T. Engelmann of Boston.

The Address of Welcome was delivered by Dr. Joseph Taber Johnson of Washington. He said that he had the honor of extending a hearty welcome to the members of the Society from all the members of the profession residing in Washington. He bade them welcome to all the public buildings, and urged them to stay as long as possible. This Society, which began in a very modest way one-quarter of a century ago, is the parent society of all the obstetrical and gynecological societies which are found in the larger cities, and it has a fine record of usefulness. It has done much to further original work and advanced study, and it has seen many changes in its life, among the most notable of which has been the reduction of the mortality of childbirth to the small figure of one-quarter of one per cent. Dr. Johnson then closed his remarks by reiterating a most cordial welcome.

Operation for Primary Vaginal Carcinoma.—Dr. William R. Pryor of New York read a paper on this subject. He said Freidl, in 1896, collected the statistics of only 130 cases of primary cancer of the vagina. In 1892-1893, out of 5341 gynecological cases treated in the Vienna Institution, there were only 15 cases of primary cancer of the vagina, or .22 per cent. Martin found only 4 cases in 5000 women that he examined. Vauvra of Prague collected the statistics of 8981 cases of cancer in women, and of these only 38 cases were primary in the vagina. Beigel found that in 8287 women who had died from cancer in only 14 had the cancer been primarily in the vagina, while in Myers' 266 cases of cancer in women 8 affected the vagina. In Vienna, cancer of the vagina occurs once while cancer of the uterus is found 68 times. The Prague ratio is 1 to 38. The primary cancer of the vagina usually affects the posterior wall, and it may extend back to the rectum, upward to the uterus, or involve other portions of the vagina. In the 18 cases reported by Olshausen in 13 the involvement was in the posterior wall. In both of the two cases reported by the author the growth recurred in the pelvis, involving the bowel secondarily. Olshausen's operation is generally the

method of procedure. This has been modified by different surgeons, especially by Mackenrodt. The operation consists in a blunt dissection of the vagina from the rectum, which Mackenrodt modified by using the actual cautery at the end of the dissection. The result of this operation has not been gratifying, for 90 per cent. of the cases had a recurrence at the site of operation inside of one year. This is probably due to either some of the cancerous tissue being left behind, or else leaving tissue of low vitality, which soon underwent cancerous infection, or, lastly, the germ of cancer may have become implanted on the raw surfaces of previously healthy tissue at the time of operation. The author has devised an operation which has none of the objectionable features of Olshausen's operation and at the same time has more advantages. The technic consists in the preparation of the patient in the usual manner; an incision is made in the abdomen, in the middle line from the umbilicus to the pubes. The ovarian vessels are then ligated over the pelvic brim. The round ligaments are tied off close to the brim of the pelvis and the broad ligaments split down to the level of the uterovesical fold. As the folds separate the iliac vessels and ureter come into view and the latter is then freed from the iliac artery, and held to one side by an assistant. The internal iliac artery is then tied with kangaroo tendon. An incision is now made into the vagina, anterior to the cervix, and four silk sutures are passed through the intestine at the approximation of this incision, care being taken not to make too much tension. The sutures then enter on the vaginal face of the bladder, emerge on the peritoneal face, and are tied. The distribution of the internal iliac artery is then dissected out and the obturator branch is tied so as to prevent anastomosis with the deep epigastric artery. The abdominal wound is then closed, and the patient put in the lithotomy position. Any cancerous masses are then curetted and burned deeply with the actual cautery. The vulva and vagina are then circled with an incision, which leaves the anterior vaginal wall. A blunt dissection, which removes the posterior wall of the vagina and the perirectal tissue, is then made with scissors. The levator ani muscle is divided, and also some fibers of the gluteus maximus, and the dissection is carried up to the point where the sutures are in the bowel. The wound is then sutured, leaving a small opening to act as an artificial anus. The author's two cases had good control of all but very liquid feces. The great point in this operation is to be sure to remove all of the diseased tissue. The operation has a sound anatomical basis, and its surgical basis is as follows: (1) Prevention of hemorrhage. (2) Avoidance of injury to the cancerous field until it has been cauterized and its blood-supply cut off. (3) Removal of all organs in which there is liability of recurrence. (4) The establishing of an artificial anus near the site of the normal outlet. Both of the author's cases lived for a little over a year.

Dr. Mundé of New York opened the discussion by saying that he had seen two cases of carcinoma of the vagina in which the rectum was badly involved as well. The disease area was so great that extirpation was impossible, so he curetted thoroughly and followed this by cauterizing with the actual cautery. Both of these patients lived for two years, and there was a very marked amelioration in their symptoms. He is opposed to such radical operative measures as Dr. Pryor has proposed, for the reason that they do not seem to prolong life to an appreciable extent and are, therefore, useless.

Dr. Sutton of Pittsburg said that he has but little faith in operative interference in advanced cases. It would seem to be better if we should study the pathology of cancer, especially in relation to its etiology and not to try to make any further advance in operative procedure. After its etiology has been determined its cure will become a much more simple problem.

Dr. Van den Warker of Syracuse said he felt very strongly on this subject, as his home was in the "Cancer Belt," and his experience had been that all operative measures are of very little value, especially the old method with the clamp, which in his hands had proven to be an absolute failure.

Dr. Montgomery of Philadelphia said his experience is that recurrence occurs so often, and usually so soon after the operation, that he thought it was very questionable if it was wise to operate at all. There is absolutely no plan of operative procedure which insures against recurrence, for there may be nests of cancerous tissue well above the seat of operation, and these will develop at a future date. We are at present in an experimental stage and it is not possible to predict results in advance.

Dr. Byrne of Brooklyn said that his experience had taught him that there is but very little use in attempting to remove a cancerous uterus, as recurrence nearly always took place, and the patient's life was not prolonged by the operative interference.

Dr. Reamy of Cincinnati said that he believed operations for the removal of cancer to be of the utmost value. In his practice he had had six women who had lived long after an amputation of the cervix for cancer, one of them enjoying good health for twenty years subsequent to the operation. In the larger percentage of cases the cancer cannot be cured on account of the extensive lymphatic involvement. In the bad cases it is usually best not to operate, as the patient will usually live longer without operative interference.

Dr. Dudley of New York said he had seen several cases of primary vaginal cancer and that in these cases the recurrence is sooner than when the other pelvic organs are the seat of the disease. He considered Dr. Pryor's operation to be a very good one in every way.

Dr. Pryor closed the discussion by saying that it would be only a few years before the etiology of cancer would be definitely determined and then its treatment would be much simplified.

Each case should be decided on its merits, and if an operation be indicated, it should be performed no matter what the influence might be on the friends of the patient. Either operate and go wide of the disease, thus removing it all, or else do not operate. Anything less than a radical operation does more harm than good.

Fecal Fistulæ.—Dr. I. S. Stone of Washington read a paper on this subject. He said the condition is one of the most distressing and annoying of post-operative sequelæ. These fistulæ usually heal spontaneously; if they do not it is because of some definite cause which keeps them open, such as extensive peritoneal adhesions or tubercular infection. Peristalsis that is reversed or is interfered with is another frequent cause of non-healing. Among the operations available for the treatment of a fecal fistula may be mentioned (1) freshening the edges and closure by suture; (2) resection of the gut and either lateral or end-to-end anastomosis with the Murphy button; (3) Greig Smith's operation or cutting down on either side of the fistula to the peritoneum without opening it; then dissecting two inches of this away from the abdominal wall on each side or around the fistula as a centre; then withdraw the peritoneum with attached and adherent bowel far enough to easily close the fistula; (4) and the method of the author, which is as follows: An incision is made in the vagina, as for vaginal hysterectomy; the fistulous tract is then opened and a rubber tube introduced through the vaginal opening into the rectum and secured in place by suture into the wound. This tube allows the escape of all gases and some thin fecal matter during the two weeks it is kept in position. After this time the sinus is washed out daily with weak formalin solution and, finally, the tract closes permanently. He has done this operation twice and in each of the two cases with the most gratifying results.

The following conclusions were drawn: (1) In all resistant fistulæ we must for obvious reasons remove any foreign body that may be present. (2) All attempts at skin closure or by cauterization or curettement of persistent fecal fistulæ are generally unsuccessful. (3) In all cases where a fistula connects with a superficial coil of intestine the method of Greig Smith may be tried before resorting to a radical operation. (4) In the deep-seated fistulæ requiring abdominal section, we must choose between excision and some form of anastomosis, for we will rarely find the case so simple as to permit of inversion of the fistulous portion and direct suture. (5) In operating for such deep-seated fistulæ we must not fail to liberate imprisoned bowel and restore the normal peristalsis, permitting free motion of intestinal coils, and direct the fecal current in its proper course. (6) Finally, in a recto-abdominal fistula we should if possible convert the same into a rectovaginal fistula and secure closure of the tract before the temporary fistula is allowed to close.

Dr. Johnstone of Cincinnati opened the discussion and said that as a matter of justice to two dead men he would state that the method outlined by Dr. Stone was taught by Lawson Tait to Greig Smith. The speaker said that he assisted Mr. Tait the first time he closed a fistula in that way, and it was his (Dr. Johnstone's) seventeenth operation. Ever since 1886 he has used this method in closing every form of fistula and in one case succeeded on the third operation in closing a ureteral fistula.

Dr. Smith of Montreal said that the injection of methylene blue solution was often of great help in determining the exact course of a fistulous tract and he cited a case in which this was clearly shown. Dr. Noble of Philadelphia said that he had seen many cases of fistula all but four of which had closed spontaneously. One of these four is now healing up while the other three are tubercular in origin. In these cases the prognosis is bad, whether operation be performed or not. It is a good general rule to wait a long while before considering operative interference, for in the majority of uncomplicated cases nature will eventually effect a cure.

Dr. Dudley of New York said that clean surgery did not always prevent fistulæ, for traumatism was often an important etiological factor. In small fistulæ it is well to wait for spontaneous closure which often takes place, but in those cases where the fistula is large operation is clearly indicated. Resection and anastomosis with the Murphy button is a very good way and in his hands has proven very successful. The fistulæ of the large intestine are more apt to heal spontaneously, but large fistulæ of the abdominal wall and either the large or small intestine nearly always require operative interference for their relief.

Dr. Mann of Buffalo said that the fistulæ of the large intestine usually heal spontaneously, while those of the small intestine must be operated upon. The further up the large intestine, or in other words the nearer to the stomach, the more difficult becomes the task of securing healing. Often a small fistula can be closed by freshening the edges and approximating them with sutures, but this is not possible when the fistula is a large one. In these cases the only thing to do is to resect the gut and do an end-to-end anastomosis. Occasionally a plastic operation on the abdominal wall will result in curing a small fistula. It is especially applicable in those cases not due to the presence of some foreign body.

Dr. Stone closed the discussion by saying that he thought the members of the society were agreed as to the danger of opening the abdomen in conditions of this sort, and this should only be done after every superficial method has been employed. The deeper fistulæ along the sigmoid and the rectum are those which give the most trouble. In regard to the claim of priority made for Lawson Tait and Greig Smith in the method pursued, the speaker said he had no idea that Mr. Tait claimed this procedure.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXXVI. NEW YORK, SATURDAY, MAY 12, 1900. NO. 19.

ORIGINAL ARTICLES.

FUNCTIONAL AND ORGANIC HEART MURMURS IN INFANCY AND IN CHILDHOOD.[1]

BY ABRAHAM JACOBI, M.D., LL.D.,
OF NEW YORK;
PRESIDENT OF THE AMERICAN CLIMATOLOGICAL ASSOCIATION.

I ASK your permission to utilize the time afforded me for a presidential address by discussing a few points connected with cardiac murmurs, both functional and organic, mainly in infancy and in childhood. In the last volume of the Transactions of our Association, I published a paper on functional cardiac murmurs. I avail myself of this opportunity to again return to the same subject with a single contribution which I think of some importance. On that occasion I quoted a remark of mine of the year 1888 (*Brooklyn Medical Journal*, March) which reads: "The heart (of the infant) exhibits functional murmurs but rarely. Whenever there are murmurs present in the infant, it is safe to attribute them to organic disease rather than to mere functional disorder." The last few years have produced many contributions to the same subject, particularly in Germany. Two authors of eminence, Hochsinger and Soltmann, deny absolutely the occurrence in the first three years of life of functional murmurs. The persistent discussion of these statements, both in societies and in the journals, have, however, brought out a few instances of a murmur in the very young that may well be taken as functional. One of them I quoted last year. After all, it appears undeniable that even a single case contradicting the categoric dicta of the two eminent workers is capable of shedding light on a difficult topic.

Helen D. (colored), thirteen months of age, rachitic, was admitted to the "Jacobi Ward" of Roosevelt Hospital March 19th, with pneumonia and some pus cells in the urine. The last physical signs of pneumonia disappeared about April 6th; on the 10th there was some vaginal discharge but no gonococci were found. It disappeared after a few days. All this time there were marked remissions in her high temperature, the thermometer showing 105° F. and more in the evening, and less than 101° F., down to 99° F., in the morning. Plasmodia were not found in spite of renewed examinations which were made before quinine was administered. Large doses of the latter were then given daily up to 10 grains a day, also subcutaneous injections during the remission. Careful search for pus everywhere was negative. On April 10th a systolic murmur was heard which gradually increased and fortified the diagnosis of septico-pyeluria. Then, while quinine was continued, Credé's ointment, 1 gram daily, was used; within a day the temperature fell to 102° F. in place of 105° F., and the child appeared comfortable for some days, smiled and took food. At no time could pus be discovered. There was no dulness, and respiration had become normal with absence of any physical changes or symptoms. The murmurs grew less and could not be found on April 17th, nor afterward at any time. About the same time the temperature rose again and exhibited the same steep curves of previous weeks. The infant was evidently sinking and could not be examined closely during the last six days of her life. She died on the 23d. The autopsy revealed a recent suppurative pleurisy of the right side, surely a few days old only, and absolutely no other abscess or ulceration. The cause of the pyemic fever is unknown to me. But the subject of greatest interest to me was the heart. Here was an infant with sepsis, with a marked systolic murmur that took a few days to become quite loud; then it gradually diminished and was absolutely lost during the last six days of life. A close examination of the heart by the pathologist of Roosevelt Hospital, one of the gentlemen connected with the Pathological Department of Columbia University, revealed positively nothing abnormal in the heart. So here was a functional mitral murmur in a baby of thirteen months of age.

Neither it nor an organic murmur should, however, be mistaken for extracardial murmurs. I have seen that error committed. Extracardial murmurs in children, mostly systolic, are very infrequent in infants below two years, because at that early time the heart is larger in proportion and less covered by the lungs. When these grow, however, and in the presence of a tumor or of adhesions between the pleura and the pericardium, the murmur appears, soft or grating; is mostly heard anteriorly only; is arhythmic, not synchronous with the contraction of the heart; is strong on deep inspiration; disappears when there is no breathing, and is less audible in a recumbent than in an erect posture.

Hochsinger terms extracardial those murmurs which are now and then observed in grave anemia, mainly leucocythemia, and not infrequently with rachitic deformities of the heart. It will not do, however, to be overconsistent. In grave anemia we might well think of the myocardial structure-changes which result in irregular contraction; and in rachitis the more extensive contact of the heart with the ill-shaped chest an-

[1] President's Address.

noys the heart-muscle sufficiently to impede symmetrical contraction.

If murmurs mean organic valvular disease in most cases, the latter does not necessitate the presence of a murmur. Mitral stenosis need have no murmurs at all. Osler long ago emphasized the fact that ulcerous endocarditis may not exhibit any murmur, and that the diagnosis of the condition is thereby rendered difficult. I have seen proofs of that statement in autopsies. When the deposits take place at the insertion and not at the edge of the valves, there is, or need be, no murmur. Two months ago I lost a child two years of age who was under close observation six weeks for pneumonia, endocarditis, and, finally, meningitis of which he died. This endocarditis was diagnosticated by the usual symptoms and was marked by a loud systolic mitral murmur. The patient was in a fair way to recover from his endocarditis (pneumonia having disappeared before the heart was affected), when meningitis developed. During that recovery the murmur became gradually less from day to day until it disappeared entirely. There was certainly an apparently complete recovery from endocarditis. The specimen which I shall exhibit to you before the end of the session shows still a slight thickening of the edge of the mitral valve and isolated small thickenings at a little distance. But for these findings the murmur might have been classed as functional; as it is, there is merely a proof that a partial, probably also a complete, recovery from endocarditis may take place. That happens, perhaps, more frequently in the very young than in advanced years. For although endocarditis is very frequent at an early age, valvular lesions are mostly—but mostly only—milder than in the adult, and compensation is easier. Moreover, murmurs are not so apt to be loud because the vessels are relatively wide compared with the heart. At about puberty the relation of the width of the blood-vessels to the volume of the heart is 61:290, while in the newly-born it is 20:25, *viz.*, almost identical.

What I said of the possibility of a bona fide recovery from endocarditis is mainly due to the changes I alluded to last year. I spoke of Bouchut's proliferating endocarditis *(endocardite végétante)*, called valvular nodes by Albini, blood-cysts by Luschka and Parrot and lately (1898) blood-nodules by Berti. They are small elevations, principally on the lower side of the valves, and give rise to a systolic mitral murmur in the newly-born, which may either last a lifetime or disappear in time with the growth of the organ, or with increasing absorption, or with progressing compensation.

Endocarditis is not always easily diagnosticated. That there may be valvular lesions without a murmur, I think I have shown. However, endocarditis does not necessarily mean valvular lesion, nor does it necessarily imply dilatation and accentuated pulmonary sound; nor is it followed, at least for years, by obstructions and disturbance of compensation, for in the very young the right ventricle is more muscular, expels its contents more readily into the blood-vessels, which are still disproportionately wide, and thus protects the auricles against dilatation. But what endocarditis does accomplish in many innocent-looking cases is through its complication with myocarditis.

Most murmurs mean organic lesions either in the valves or in the myocardium. In that respect all ages are alike. But there are possibilities in the infant which modify the explanation of the usual observations; and there are conditions in which the diagnosis may be very difficult. For instance, besides the frequent mitral systolic murmurs that result from infectious diseases, most commonly from rheumatic invasion, there are those that originate in contraction, or more or less obliteration of the mitral orifice, or adhesion of the valve. These conditions are not always complicated. There is, for instance, the case of Gerhardt, that of a baby who died at the age of four months. Still, they are very rare, very much more so than in the pulmonary artery, or even in the aorta where some have been noticed and ascribed to syphilis.

In persistence of the ductus arteriosus Botalli there is a loud systolic murmur over the sternal end of the second left intercostal space. It extends upward into the vessels of the neck mainly of the left side and is audible posteriorly in the left interscapular space. It is connected with a characteristic dulness nearly oblong, extending along the left margin of the sternum to the clavicle. Within a few months lately I have seen two cases in which the diagnosis was obvious. But uncertainty may arise when there are complications with valvular anomalies (either rudimentary development or excrescences) or with interauricular communications, or with stenosis or atresia of the aorta or of the pulmonary artery, or with a narrow bicuspid orifice. These complications are more dangerous than the patency of the channel itself, because the number and degree of accompanying conditions, such as extensive murmurs, cyanosis, and hypertrophy of the right ventricle, depend on them. When not so complicated, patency of the duct is compatible with a fairly long life.

In congenital stenosis of the pulmonary artery there is in the sternal part of the second left intercostal space a systolic murmur which is not transmitted into the carotid, except when there is a complication with defects of the ventricular septum. It may be mentioned that the second pulmonary sound is feeble, that there is cyanosis with clubbed fingers and hypertrophy and dilatation of the right ventricle. These are not present when, instead of stenosis, there is a complete atresia of the artery. In that case the right heart is small or rudimentary.

Absence of the ventricle I have never seen or diagnosticated unless complicated with stenosis of the pulmonary artery. In these latter cases there is a loud murmur over the sternum which extends far down and upward into the vessels of

the neck. The secondary pulmonary sound is accentuated only when there is a hypertrophy of the right ventricle; when both ventricles are hypertrophied the second aortic and pulmonary sounds are of equal strength. The frequent statements in the books that pulmonary stenosis with defect of the septum is characterized by hypertrophy of the heart, I cannot verify. On the contrary, the absence of much hypertrophy I find to be characteristic of that condition; it has led me to a correct diagnosis which I could verify by the autopsy. The record of one such case may be found in the *Archives of Pediatrics* of a number of years ago.

Another class of cyanotic cases owes its origin to an arrest of development of the common arterial trunk which did not separate into the aorta and pulmonary artery. In these cases, contrary to many statements, I found but little hypertrophy or dilatation, sometimes none at all. The loud murmur is heard over the sternum a little to the right and to the left, about the insertion of the second and third ribs; it is very audible posteriorly, but much less than anteriorly.

Very loud murmurs, audible at a distance, without the ear touching the chest, I have heard more in adults than in children, without having an opportunity to make an autopsy. They are always systolic and are mostly attributed to hypertrophy and believed to be muscular only. In a few cases, however, I am certain that no increase of percussion dulness or of cardiac impulse corresponded with the loudness of the tone; so I was inclined to believe that the peculiar phenomenon was due to torn and swinging papillary muscles. Not infrequently the general condition of the patient is vastly better than the formidable noise would appear to suggest.

Organic murmurs, when present, are not always audible. They may not be heard at all when the heart-beats increase in number. Then the blood-wave is small and the excursion of the valve short. Diminution of temperature, or a few doses of digitalis, therefore, restore a murmur which was temporarily absent; but under ordinary circumstances also, as I said before, an organic murmur may disappear for two reasons, one of which is recovery, the other compensation. I think I proved that the disappearance of a murmur, as, for instance, in Case III. and Case IV., described by Starck in *Arch. f. Kind.*, 1900, p. 200, does not prove it to be functional. Nor is there any reason why an endocarditic thickening should not be absorbed as well as those on other tissues.

A few words only on myocardial changes. About middle-age myocardial changes are mainly caused by everything that gives rise to hypertrophy and dilatation. We find mostly a diffuse increase of the intermuscular connective tissue with atrophy of the muscular tisue which first was hypertrophic. The senile heart is very apt to exhibit hypertrophy and dilatation of a peculiar type. There is atheromatous degeneration of the coronary and the minute nutrient arteries. There is consequently an annoyance or destruction of the lymph interstices and channels in and on the myocardium, and of the two large trunks that carry the myocardial lymph to the mediastinal lobes, and, finally, degeneration of the myocardium resulting in either macroscopic, more or less local, thickening or in atrophy. That is why the contraction of the organ is liable to be irregular, and partial, in instalments, as it were, although there be no accompanying sclerotic alteration of the pericardium, or thickening of the valves and of the endocardium.

What we call debility of the heart is a symptom of a great many different conditions. There is a congenital atrophy which is liable to lead to lipomatosis, there are intoxications by infectious diseases, alcohol, syphilis, malaria, and tuberculosis; nutritive disorders, such as rachitis and scrofula, overexertion and premature schooling with constipation, and subacute and chronic nephritis, one of the most frequent and most frequently overlooked diseases of early infancy. I mention only those causes of myocardial acute, subacute or chronic changes that are most common in the young, but should emphasize that what is called debility or failure at any age is in all the cases so occasioned not functional, but the result of organic lesions. Two most interesting cases of heart debility I found connected with purpura. Only in one could I obtain an autopsy. There were numerous blood-points in the walls of both ventricles and a livid appearance of the muscle.

In infants and children myocarditis is mostly parenchymatous.

Most intense and persistent myocardial changes are found after influenza and after diphtheria; they are most injurious at about puberty—fortunately, however, diphtheria, is not so frequent at that age—when the heart is no longer disproportionately strong and large, than in earlier years. Schmalz reports 81 cases of chronic cardiac disorder originating in 500 cases of diphtheria. In some seasons—for instance, in the severe New York epidemics of 1870 and 1874—the proportion was much larger. In many arhythmia and murmurs last for life; they may be modified by a protracted recumbent position during convalescence, and by resorting to absolute rest extending over weeks whenever increased cardiac disturbance is observed. The systolic murmur is *extensive*, but mostly heard in the mitral and pulmonary regions, at the same time that now and then there is an increase of transverse dulness. But more characteristic than the extensive murmur, which often by the absence of localization facilitates the differential diagnosis, is the irregularity of the contraction of the heart. The condition of the heart-muscle changed by myocarditis (parenchymatous or hyperplastic, it makes no difference) is not uniform. Neither a kidney nor the myocardium is equally affected and changed in all its parts. That is why arhythmia is so frequent. No matter how many causes, either in the heart or nerves

or distant organs, are charged with causing it, the most frequent cause is chronic myocarditis.

A peculiar form of arhythmia mostly complicated with a murmur is the duplication of one of the heart-sounds. It is not always easy to distinguish which of the sounds it is that is so affected. Now and then we hear a dactylus—uu, in other cases or at other times an anapestus uu—. The cause of this gallop-rhythm must be either in the myocardium or in the valves. From careful and long observation of individual cases, and from the improvement that rest alone is able to work on the case in regard to the annoying symptoms, there is no doubt in my mind that it is the former. The first sound appears to slit up when the two atrioventricular valves are not working simultaneously, the second, when the aortic and the pulmonary valves do not act together. This lack of synchronicity, however, depends on the lack of muscular myocardial coaptation. A similar symptom may be had in mitral stenosis, particularly after a slight exertion, and in hypertrophy and dilatation of the right ventricle when the valves close in different times.

The gallop-rhythm is a suspicious symptom inasmuch as it proves the exhaustibility of the heart-muscle. I kept the children in bed for months, and a single exertion sufficed to renew or to increase the duplication. Thus, a long rest is required and attention to general hygiene, food in small and digestible quantities, and regulation of the bowels. In most cases iodide of potassium is indicated and strychnine or some other cardiac stimulant. Strychnine should not be feared, because it should not be forgotten that parts of the heart are probably in an intact or nearly intact condition, and permit of stimulation. If that be done carefully, the galloping rhythm ceases to be such a bad omen as some declare it to be.

Clara R. was discharged June 8, 1899, after having been in the hospital for chorea. This returned about the end of January, 1900, she then had pneumonia, from which she recovered. She was readmitted March 3, 1900, with chorea mostly of the right upper extremity, very irregular heart-action, dulness reaching more than one centimeter beyond the right margin of the sternum, while in an erect position, and marked duplication of the second sound at the apex and to the right of it. The impulse was feeble. Radial pulse small. Muscular power generally feeble, with costiveness and at one time incontinence of urine resulting therefrom. The latter was almost suddenly relieved by increasing the doses of $^1/_{100}$ of a grain of strychnine to $^1/_{50}$ of a grain, three times a day. When her general strength improved and her color brightened, the duplication disappeared gradually; but whenever her condition appeared worse, under the influence of a low barometer, for instance, it would reappear. She was kept in bed and was discharged April 16th without her duplication, and with her heart not reaching beyond the median line of the sternum when in a sitting posture.

This Association fills a place peculiarly its own. Its aims and objects appear sympathetic to every physician who is more than merely an anatomist or pathologist, and better than a mere prescription-writer. The class of philosophic doctors whom Hippocrates calls "godlike" because he says they strive to learn the connection of things, belongs here. The climatic and atmospheric influences of Nature on man, mainly as they affect the human creature through the respiratory and circulatory organs, is the object of your study. That is why there is, and should be, a peculiar incentive to become a member and why the applications for admission were always very numerous, and the roll of membership has become large. We have been very fortunate in not losing by death any of our members, except Dr. J. C. Mulhall of St. Louis, whose loss we have to deplore.

The danger of swelling the ranks too rapidly is very great indeed. This year, however, we are singularly fortunate in the character and standing of our candidates. In connection with this matter, it is hardly necessary to point to and to emphasize the established policy of the Association to admit only men whose position is established or who through at least a few publications connected with our study have proved their right to apply.

Feeling as I do that contributions should be spontaneous unless there be a preparation for a set discussion, I felt a few months ago that there might not be a sufficiency of material for your meetings. I was happily mistaken, for there is ample work for you. The American democratic spirit has prevailed again.

PERFORATING DUODENAL ULCERS.

By ROBERT F. WEIR, M.D.,
OF NEW YORK;
PRESIDENT OF THE AMERICAN SURGICAL ASSOCIATION; SURGEON TO ROOSEVELT HOSPITAL.

(Continued from p. 696.)

The following list embraces all the reported cases of perforation of the duodenum that have undergone operation up to April, 1900, and have been carefully investigated and epitomized by Dr. E. M. Foote, to whom I am much indebted for this and other help in the preparation of this article.

Case 1.—M., aged thirty-five years; a heavy drinker; no history of indigestion. For a week or so loss of appetite and indefinite epigastric pain; then sudden acute pain while at work, followed by vomiting. Two days later brought to hospital in collapse. Abdomen distended, dulness in right flank; pulse rapid and feeble; temperature 98.8° F. Laparotomy at end of two days. Acute peritonitis—cause not discovered. Death in a few hours. *Autopsy:* Perforation anterior wall of duodenum close to pylorus.[1]

Case 2.—M, aged thirty-one years. Acute attack like intestinal obstruction. Diagnosis, ap-

pendicitis and general peritonitis. Operation third day. Appendix normal; general peritonitis; perforation not found. Death in a few hours.[2]

Case 3.—M., aged twenty-nine years; history of abdominal colic. While in usual good health he was seized at 5 P. M. with sudden pain, followed by bilious vomiting. Some lumps of feces and gas passed that evening, but there was absolute constipation thereafter. Next day a purgative only increased the vomiting and pain. Entered hospital on third day, with fecaloid vomiting. On fourth day great distention, tenderness and pain at its maximum in right hypochondrium; pulse 120, small; dulness in both flanks. Diagnosis, perforative peritonitis. Operation in about ninety hours. General peritonitis. The hand thrust under the liver broke into a cavity containing two quarts of serous liquid. The intestine was searched in vain for mechanical obstruction, and on account of weakness of patient, the operation was terminated. Death same evening. *Autopsy:* Perforation "near the end of the second portion of the duodenum, externally."[3]

Case 4.—M., aged twenty-eight years, always well. While drinking tea, had a violent pain in the left side of the abdomen. Next day, a tumor to the right umbilicus; sour vomit, later becoming fecal; tympanites; constipation; no blood. Third day, temperature normal, pulse about 130. Opération in eighty hours (about). Incision to left of umbilicus gave vent to gas and pus; intestine sound; greatly distended; incision of intestine; suture of collapse; drainage. Death in seven hours. *Autopsy:* Perforation in anterior wall of duodenum purulent peritonitis.[4]

Case 5.—M., aged forty-one years, of good previous health except slight indigestion. One year before perforation, had an attack of abdominal pain with constipation. While at work was seized with violent pain; gastric vomiting, later becoming fecal; no blood; absolute constipation. In tympanitic stage, when first seen by reporter; respiration thoracic; pulse 120; temperature 99.2° F. Diagnosis, septic peritonitis. Operation, May, 1891. Usual incision; cavity searched; no cause for suppurative peritonitis found; irrigated; drained. Death in ten hours. *Autopsy:* Perforation in posterior wall of duodenum, 1 inch below pylorus, freely communicating into peritoneal cavity when intestines were lifted.[5]

Case 6.—F., aged twenty years; servant; of constipated habit; otherwise health good. Bowels moved by salts two days before the attack. A sudden attack of pain in the right hypochondrium, passing then to left side, and afterward becoming general. Vomiting of sour fluid began twelve hours after the attack of pain and continued. There was tympanites without loss of hepatic dulness.. Diagnosis of general peritonitis, cause unknown. Operation in twenty-four hours. A median incision below the umbilicus allowed the escape of inoffensive fluid. A second incision above the umbilicus disclosed the perforation ¼ of an inch in diameter, in the posterior aspect of the duodenum, close to the pylorus. Milk was escaping through it. The ulcer was excised and sutured, the abdomen flushed. Death in six hours. General peritonitis.[6]

Case 7.—M., aged twenty-one years; always good health. Sudden pain in the lower abdomen, followed by vomiting and collapse. After eighteen hours laparotomy gave exit to much brownish, acid, non-feculent fluid. There was adhesive peritonitis. The cause of peritonitis was not found. Death in a few hours. *Autopsy:* A perforation in the anterior wall of the duodenum, about 5 inches from the pylorus, and about 5 inches in diameter; a second non-perforating ulcer of the posterior duodenal wall.[7]

Case 8.—M., aged fifty-six years; brought to the hospital in a condition of tympanites, and having a right inguinal hernia. Laparotomy. The hernia was explored and found to be in good condition, and the incision was prolonged upward seven inches giving vent to purulent and fecal fluid. No cause for the peritonitis was found about the cecum or elsewhere. Death in a few hours. *Autopsy:* On the anterior surface of the duodenum, 0.5 inch from the pylorus, was a perforated ulcer, 0.5 by 0.7 inch. It could easily have been sutured.[8]

Case 9.—M., aged twenty-eight years; of good health until two months before perforation, did not feel quite himself, but no localized symptoms. While ascending an omnibus, felt a sudden pain in the abdomen; nausea and vomiting after an emetic had been given; constipation for four days, then a little fectal matter and flatus, after an enema. Entered hospital on seventh day; abdomen distended; general tenderness; respiration 28; thoracic: pulse 104; temperature 99.8° F. Questioned with reference to duodenal ulcer; could not localize first pain; never any blood by mouth or in stools; only slight history of indigestion. No evidence of trouble in upper part of abdomen. Diagnosis, septic peritonitis with pus in pelvis. Operation in one hundred and fifty hours (about). Subumbilical incision; two pints of pus from pelvis; appendix, cecum and small intestine sound; higher search abandoned as there was less peritonitis in that direction; irrigation, drainage, suture. Death in fifty-four hours. *Autopsy:* Septic peritonitis in pelvis, and also about duodenum, these areas being separated by a middle zone, relatively free from peritonitis; perforation, 0.5 inch in diameter, 0.7 inch from the pylorus, in the upper wall of the duodenum.[9]

Case 10.—M., aged sixty-one years, with a long history of gastric ulcer, with epigastric pain and vomiting, never of blood. Sudden pain in right hypochondrium; collapse. Diagnosis, perforation of gastric ulcer. Operation in four hours, fifteen minutes. Perforation in duodenum, anterior wall, 0.7 inch from pylorus, sutured; thorough washing, drainage. Death in six days. *Autopsy:* Suture tight; a second ulcer in the back of the duodenum, non-perforating; purulent fluid behind liver and in pelvis.[10]

Case 11.—M., aged twenty-eight years; good

health. One hour after a movement of the bowels, while lifting barrel from a dray, felt a sudden pain across the abdomen like a knife; vomiting immediately began and continued; third day fecal vomiting; pain especially on right side; pulse rapid, temperature 100.6° F., respiration rapid; cold sweat. Diagnosis, intestinal obstruction. Operation in sixty-two hours. Subumbilical incision gave vent to a large amount of sero-pus with a fecal odor; cecum, appendix, hernial openings, and intestine in pelvis examined; incision prolonged upward; perforation as "big as a florin" in anterior wall of duodenum; 1 inch from pylorus, pared and closed with six or eight Lembert stitches. Area covered by omentum; irrigation; drainage in pelvis. Death in eight hours. No autopsy.[11]

Case 12.—F., aged twenty-seven years; for a fortnight had epigastric pain, and constipation for seven or eight days; treated for indigestion. Sudden pain in epigastrium and collapse; vomiting frequently repeated. Thirty hours later; slight tympanites; abdomen uniformly tender; pain most marked in epigastrium; vomiting; respiration rapid and irregular; pulse 120; temperature 100.6° F. Diagnosis, general peritonitis from mechanical obstruction. Operation in thirty hours (about). Subumbilical incision gave vent to fluid and fibrin; intestinal coils congested; no lesion found; incision prolonged upward; gas noticed near gall-bladder; perforation of duodenum 0.7 inch from pylorus; surrounding induration incised; suture; irrigation; sponging; no drainage. Nothing by mouth for seventeen days. Recovery. Two months later symptoms of obstruction; operation on third day; adhesions which obstructed the ileum a short distance above the cecum freed. Death from perforation of the wall of the ileum just above the obstruction. The suture of the duodenum was smooth and thin.[12]

Case 13.—M., aged thirty-five years, of alcoholic habit. Upon going to work was attacked by sudden abdominal pain and vomiting; pain and nausea continued, although vomiting ceased. Thirty hours later the patient lay with hollow eyes, alternately extending and drawing up his legs as paroxysms of pain came on. Nothing had passed by anus. There was tympanites except for dulness in the right iliac region, where pressure was painful. No tumor could be made out; temperature 37.9° C. (100° F.), pulse 104 and small. Operation by Brissaud, fifty-one hours after the attack, December 14, 1893. An incision was made over the appendix, giving vent to a great quantity of fecal matter. The appendix was not seen; drainage. Death in a few hours. *Autopsy:* General peritonitis, and a fusiform collection of pus from the liver to the right iliac region. There was perforation of an ulcer in the anterior wall of the duodenum, just below the pylorus.[13]

Case 14.—M.; after a debauch the patient was attacked by a sharp pain in the right side of the abdomen. Forty-eight hours later there was general tympanites, dulness over a tumor in the right iliac region and collapse. Operation in fifty-three hours as for appendicitis. From the incision pus and milky fluid escaped in large quantities. Irrigation and drainage. Death. *Autopsy:* Perforated duodenal ulcer, the sac about the cecum containing much of the milk and food which had been taken during the illness.[14]

Case 15.—M., aged twenty years; slight indigestion. While at the theater a sudden attack of severe pain in the epigastrium with tenderness; no vomiting; passage of flatus; slight tympanites; temperature 96° F., pulse 100. On the second day greenish vomiting, becoming fecaloid; obstipation; rapidly increasing tympanites; tenderness in the cecal region. Diagnosis of appendicitis. Operation in about sixty hours. Gas without odor, thin, purulent fluid, and lymph in peritoneal cavity. Perforation not found; intestines washed; abdomen closed. Death in twenty-four hours. Perforation anterior aspect of first portion of duodenum.[15]

Case 16.—M., aged twenty-three years; an attack of sudden pain, vomiting, and obstipation three years previous. An acute attack of pain and vomiting lasting five days. There were two movements of the bowels in this period. When seen on the sixth day, there was marked tympanites and a very rapid pulse, but not much tenderness or pain in the cecal region. Diagnosis of appendicitis. An incision made about one hundred and five hours after attack allowed odorless gas and thin pus to escape. The intestinal coils were covered with lymph and greatly distended. An incision into the jejunum permitted several pints of fluid to escape. Perforation not found. Abdomen washed and drained. Death in twenty-two hours. *Autopsy:* There was a small perforation of the anterior wall of the duodenum, one half inch below the pylorus. At the same distance, there was in the posterior wall the scar of a healed ulcer.[16]

Case 17.—M., aged twenty-eight years, hard drinker. Sudden abdominal pain accompanied by vomiting. Two days later admitted to hospital with general abdominal distention and tenderness, but no loss of liver dulness: temperature 103° F., respiration 20, pulse 120. On the third day a liberal median incision revealed a general peritonitis, with a small amount of fluid; cause not found. Rapid irrigation and drainage. Death three days after operation. *Autopsy:* Sharply defined ulcer in the third part of the duodenum, in its posterior wall. The ulcer had for its base the pancreas, whose tissues were necrotic and infiltrated with pus. The suppuration had extended as far as the jejunum, and had there entered the general peritoneal cavity.[17]

Case 18.—M., aged thirty-five years, a hard drinker, with a history of a similar attack thirteen years previous. For a few days there was a severe abdominal pain accompanied by vomiting. Was admitted to the hospital with very great general tenderness, no distention, and a temperature of 102° F. The symptoms improved until the fourth day after admission, and then signs of a

rapidly spreading peritonitis were manifest. Diagnosis of appendicitis. Incision made on the fourth day over the appendix showed that organ to be normal. There was a general peritonitis and a large quantity of odorless fluid in the abdomen. Drainage. Death in a few hours. *Autopsy:* Perforation in the superior wall of the first portion of the duodenum just beyond the pylorus. The gut was adherent to the liver by recent fibrin. There was also the scar of an old healed ulcer.[18]

Case 19.—M., aged fifty-six years; long history of gastritis and diarrhea and sometimes of blood. Acute attack of pain, four hours after dinner; constant vomiting; collapse. The usual lavage failed to give relief and the water did not return readily. Morphine administered; passage of gas per anum. The next day the symptoms disappeared, then returned with vigor. Stool after enema. The second day there was again a remission and again a relapse toward night. Dulness and pain most marked in the right iliac fossa; pulse 112, temperature 38.2° C. (100.7° F.). The third day still iliac tumefaction; marked sepsis; pulse 160. Operation sixty-six hours after attack. Incision over appendix, which was thought to be the origin of the disease, allowed the escape of three pints of reddish purulent fluid with fibrin masses. The peritonitis appeared limited, and it was decided best not to break up the adhesions to find the perforation. Douche and drainage. Death nine hours after operation. *Autopsy:* An ulcer just below the pylorus occupied two-thirds of the circumference of the duodenum, the anterior wall being not involved. The perforation was on the postero-external surface.[19]

Case 20.—M., aged thirty-three years; no previous gastric trouble. Sudden colicky pain in right hypochondrium; collapse; no defecation nor passage of wind. Following day, tympanites; liver dulness absent; temperature 100° F., pulse 122, respiration 38. Operation in twenty-five hours. Incision median line; purulo-fibrinous peritonitis; gas and fluid from duodenal region; perforation sutured by two rows of stitches; intestines cleaned by moist gauze; no drainage. Recovery after bronchitis; primary union of wound. Patient seen four years later in good health.[20]

Case 21.—M., aged thirty-five years, a hard drinker. Sudden severe abdominal pain, without vomiting. Admitted to the hospital eight hours later with a tense abdominal wall, and tenderness over the gall-bladder. The pulse was 90, but there was no fever. Later the temperature rose, distention with obliteration of the liver dulness developed. Diagnosis, appendicitis. Operation in twenty hours. Incision over appendix, which was normal. A well-marked general peritonitis was present, but the patient's condition prevented further search. Death in twenty-four hours. *Autopsy:* Perforation of the duodenum in the posterior wall 1¼ inches from the pylorus, and a second non-perforating ulcer lower down.[21]

Case 22.—M., aged fifty-two years; attack of acute pain in epigastrium with obstipation and tympanites six years previous. Recovery in six weeks. More or less pain since. Acute attack of severe pain about pylorus, later extending downward and backward. Absolute obstipation; tympanites slight on second day and increasing; vomiting on third day of moderate character; temperature 100° to 100.5° F. Diagnosis of appendicitis. Operation on fourth day. Intestines distended and covered with lymph; no pus. Perforation of duodenum into general peritoneal cavity found and closed. Cavity douched with hot water; gauze drain. Thirst and brownish vomiting; rapidly rising temperature. Death on third day after operation. No autopsy.[22]

Case 23.—M.; sudden epigastric pain while at work, followed by vomiting, tympanites, and loss of liver dulness. Operation in about thirty hours. Perforation in anterior wall of first portion found and sutured. Gas and yellowish fluid in peritoneal cavity. Flushing with hot water; drainage for twenty-four hours. During convalescence return of symptoms necessitated a second laparotomy. Only adhesions of liver to diaphragm. A needle thrust through the eighth intercostal space into these drew a drop of pus. A mural abscess formed later which probably caused the above recurrence of symptoms. Recovery.[23]

Case 24.—M., aged fifty years, who for ten or fifteen years had pain after meals, with vomiting and bloody stools. Last hemorrhage seven months before entrance to hospital. Emaciated and anemic on entrance; stools black; diagnosis of ulcus ventriculi. Two days later sudden pain in right hypochondrium, with retracted abdomen; temperature 100° F., pulse-rate normal. The signs of peritonitis with feelings of distention increasing, laparotomy was performed twelve hours after the attack. A long incision made above the umbilicus with cross-cut to the left and right; stomach and duodenum examined and fluid like coffee-grounds squeezed from its posterior region by pressure, but no perforation could be made out. Duodenum, stomach and colon were sutured together to protect the general peritoneal cavity. Cavity irrigated and wiped and drained at epigastrium and through pelvis. Recovery. Six months later in good condition, as far as duodenal ulcer went. Still had chronic gastritis. Death in eight months from operation for suppurative peritonitis. *Autopsy:* A new perforation in the posterior wall at the beginning of the second portion of the duodenum.[24]

Case 25.—M., aged twenty-four years, with no gastric trouble. After a large dinner he felt indisposed for a few minutes. The next morning he rose at six o'clock in usual good health and ate his customary breakfast. At the last mouthful of a glass of white wine, he felt a sudden most severe pain and lay down in bed. There was vomiting of food, and afterward incessant vomiting of bile. He described the pain as "not like a general colic, but always in one point, here,"

indicating a spot on the left, midway between the umbilicus and ensiform. A physician diagnosed volvulus, and tried by enemata and massage to relieve the pain. In five hours vomiting ceased and the pain subsided somewhat and was referred to the lower abdomen. No fecal matter nor gas passed the anus. There was no tympanites nor difficulty in passing water. Sixteen hours after the attack he was admitted to the hospital. The abdomen was retracted and board-like, the pain was less and vomiting had ceased. There was costal respiration and the expression of the face indicated severe abdominal trouble, the nose pinched, the eyes sunken, the hands clammy and the patient in a half stupor. Diagnosis was thought to lie between appendicitis and duodenal perforation. Nineteen hours after the attack an incision was made in the median line from the pubis to above the umbilicus. The abdomen contained non-feculent fluid, and there were light adhesions on the intestinal coils. Appendix normal; no intestinal lesion; pelvis normal. Incision prolonged upward and stomach searched; gas found escaping from under liver, and perforation near pylorus on anterior surface of duodenum sutured. Abdomen wiped and drained from site of duodenum. Several saline injections amounting to 4200 c.c. in all. Death in twenty hours from peritonitis; suture tight.[25]

Case 26.—M., aged twenty-six years; health perfect, never any gastric symptoms. Two hours after his usual light breakfast, while making a slight effort to open a sack, the patient experienced an intense pain in the left side of his abdomen. He was taken almost at once to a hospital. Diagnosis of appendicitis; treatment by ice and opium. Following day a feeble pulse, without fever; abdomen distending; tenderness in left iliac fossa. On second day vomiting set in becoming bloody and bilious. About fifty-six hours after the attack, Sebileau made an incision as for appendicitis, permitting the escape of non-feculent fluid, like bouillon. The appendix was normal. The patient was already collapsed, and nothing further was done, except to drain with gauze and give a saline injection. Death after incessant vomiting in thirty hours. *Autopsy:* Abdomen contained fluid. There was general peritonitis; perforation in the anterior wall of the duodenum 1 cm. from the pylorus.[26]

Case 27.—M.; an attack of sudden pain like lead colic. Incision from the ensiform downward. There was food under the liver, and a perforation was found in the first part of the duodenum. Suture. Death in twelve hours.[27]

Case 28.—M., policeman, of alcoholic habit and history of gastric attack. While on duty the patient had a sudden attack of pain which made him writhe in agony. His bowels had moved a short time before. When seen soon after the abdomen was retracted, as hard as a board, excessively tender, especially under the ribs and in the right flank. Diagnosis of hepatic colic. Compresses were applied and morphine administered. The following day he felt better. An injection resulted in a large stool. Milk and vichy were administered. There was no fever and not much pain, but the abdomen was still retracted. Thirty hours after the attack vomiting set in, soon becoming bilious. The abdomen swelled and the patient was taken to a hospital. Diagnosis, appendicitis, intestinal obstruction or volvulus. Abdomen opened forty-eight hours after the attack. Nothing but general peritonitis discovered. Dieulafoy, operator. Death in one hour. *Autopsy:* Perforation of the duodenum in the anterior wall just below the pylorus.[28]

Case 29.—F., aged twenty-five years, servant, giving history of gastric trouble with vomiting, but never of blood. An increase of gastric pain, with general tenderness and abdominal swelling. Was followed four days later by marked distention. Palpation showed the greatest tenderness to be in the cecal region. There was no fever. A needle thrust into the right iliac fossa brought out gas and an odorless fluid, containing flakes of fibrin. An incision was made over the appendix which was congested. There was general peritonitis. Death four days after the operation. *Autopsy:* Pus in the pelvis and about duodenum, in the lower wall of which close to the pylorus there was a perforated ulcer. A second ulcer was situated in the posterior wall.[29]

Case 30.—F., aged thirty-four years, servant, with a history of gastric troubles for twenty years, with frequent vomiting of blood; last attack one week before admission to the hospital, the vomiting being followed by bloody stools, pulse 84, regular, strong; rectal temperature 98.6° F. Maximum pain midway between ensiform and umbilicus to the right of the median line. Ice-bag on abdomen, nothing but ice by mouth. Next day pain involved the whole right side; was relieved by morphine, but recurred with vomiting, a small pulse of 106, and cold sweat. More morphine was given. Two hours later the pulse was 130, there was tenderness all over the abdomen, and edema in the epigastrium. Diagnosis, gastric ulcer. *Laparotomy two days after admission to the hospital* (thought by the operator to be "at least fifteen hours after perforation") through the left rectus above the umbilicus; gas and fluid escaped; no adhesions; general peritonitis. Perforation at pylorus, thought to be in the lesser curvature, sutured. Abundant irrigation; gauze drainage; 700 c.c. saline injected. Death twenty-four hours after operation. *Autopsy:* Perforation in the superior wall of the duodenum near the pylorus. The suture was perfect.[30]

Case 31.—F., aged fifty-four years, with history of indigestion, no bloody vomiting. A sudden attack of pain and vomiting, not of blood, followed by a large bloody stool and several small ones of a tarry character. Was followed eighteen days later by a second attack. There was tenderness and resistance to the right of the median line above the umbilicus; no fever. Laxatives and enemata relieved the abdomen of gas and fecal matter and the area of resistance became

a well-defined tumor. Nine days after the last attack an incision was made through the right rectus muscle, and in separating the abdominal wall from the viscera, several small abscesses were opened, and through one of these gas and gastric contents escaped. Perforation readily found and closed. It was at the pylorus and thought to be in the stomach. The gall-bladder was opened and eight stones removed. Most of the omentum was excised. Iodoform-gauze drains were inserted. Death in five weeks. *Autopsy:* Abdominal condition was perfect. Death was due to pulmonary thrombosis infarction from saphenous thrombosis. The sutured ulcer had healed. Two others in the duodenum had not perforated.[31]

Case 32.—M., aged thirty-seven years, shoemaker, with nausea and vomiting and indigestion more or less for years. One morning he awoke feeling perfectly well. On sitting up in bed he was seized by a terrible pain in the umbilicus and to the right side lasting several hours and followed by vomiting. Enemata resulted in several small stools. The next day he was taken twenty-five miles in a sleigh to the hospital, where he arrived with respiration 26, pulse 150, temperature 102.5° F., but free from pain while at rest; tenderness in left iliac fossa, in right hypochondrium, and over right rectus muscle. Stomach and bowels washed out. Diagnosis of duodenal ulcer or appendicitis. Sixty hours after the attack an incision was made in the median line, mostly below the umbilicus. Fluid and gas and fibrin escaping mostly from above, the cut was extended upward and the right rectus was cut across. A perforation which admitted the index finger was found in the anterior superior wall of the duodenum near the pylorus. It was sutured and the cavity washed out with water at a temperature of about 45° C.; wiped out and drained in both loins as well as about duodenum and liver. Compresses wrung out of hot saline were placed in the wound which was left open. The pulse and temperature gradually rose, and in spite of 1150 c.c. of salt solution injected into a vein, the patient died twenty-six hours after operation. *Autopsy:* Fibrous peritonitis without fluid. The suture was firm. There was an abscess between the stomach and colon.[32]

Case 33.—M., aged forty-six years, while lifting a heavy weight, felt something snap and immediately afterward there was intense pain (locality not given), which soon spread to the whole abdomen. Four days later he entered the hospital, not having passed gas or fecal matter per anum. There was no localized pain, but pressure was everywhere painful; no tumor nor fluctuation. The patient had not vomited but had a hiccough; pulse irregular, 110; temperature 99° F. A diagnosis of intestinal obstruction was made and castor oil was given in small doses every hour. The next day there was great prostration, and choreic movements. Five days after the attack the abdomen was opened by a median incision from pubis to ensiform, with a cross-cut through the right rectus muscle. There was a general peritonitis with pus and membranes all over, but especially in the pelvis. At the pylorus on the superior surface was a large perforation which was sewed with difficulty, and the abdomen flushed and closed. Death two hours after the operation.[33]

Case 34.—F., aged thirty years, with a history of indigestion and some epigastric pains. While eating breakfast she was seized with terrible pain in the epigastrium and left the restaurant for a seat in the park close by. She was taken at once to a hospital. In six hours the pain was general and vomiting set in. The following morning she was worse, without stools or passage of gas, and scanty urine. The condition grew rapidly worse, with rapid pulse, subnormal temperature, tympanites and loss of liver dulness. A diagnosis of perforation, probably of the stomach, was followed by operation twenty-eight hours after the attack. Incision above the umbilicus gave escape to gas and a quart of bile and purulent fluid. Stomach and biliary tract normal, and perforation found in the right side of the second portion of the duodenum. Opening sutured and abdomen closed over a rubber drain to duodenum. Death in fourteen hours. *Autopsy:* Perforation a little below and to the right of the opening of the common duct explained why the bile flowed so freely into the abdomen. The closure was perfect. There was a second ulcer a little below the first which had not perforated.[34]

Case 35.—M., aged twenty-three years, a soldier with a history of numerous sprees before he entered the army. During a march he took a cup of coffee, and almost immediately he was overcome by pain in the epigastrium and right hypochondrium, extending into the right shoulder. He was nauseated but did not vomit. There was tenderness and muscular contraction on pressure, especially on the right side. An enema produced a normal dejection. The pain spread over the whole upper part of the abdomen, accompanied by a certain amount of distention, constant vomiting of greenish fluid and a partial disappearance of the liver dulness. Incision above the umbilicus forty-eight hours after the attack. General peritonitis. Intestine overhauled, then liver examined. Bubbling at its base led to the discovery of the duodenal perforation in the postero-superior wall of the first portion of the duodenum. The right rectus was divided to give room for suturing, but the stitches would not hold, and the perforation, of a size to admit the little finger, was walled off from the peritoneal cavity by omentum sutured above and below it. Death in thirty-six hours from general peritonitis. There were no other lesions found at autopsy.[35]

Case 36.—M., aged twenty-two years. Always perfectly healthy. An acute attack of intense pain and vomiting three hours after supper; pain referred to the umbilicus and right side. On the following morning temperature 101° F.,

pulse 120, respiration 42; moderate tympanites, lower edge of liver dulness two inches above the costal margin, tenderness most marked in the epigastrium, and on the right side of the abdomen. Diagnosis of peritonitis, probably due to appendicitis. Operation fifteen hours after the onset of attack. Incision over appendix. General seropurulent peritonitis. Appendix appeared normal but was excised. A second incision above umbilicus revealed after careful search a ¼ inch opening in the anterior wall of the first portion of the duodenum, close to the hepatic ligament. It was in the center of an indurated area, and on account of its deep situation, no excision was made. Suture and cleansing of the peritoneum with gauze. Closure of abdomen over iodoform-gauze drain. Recovery with severe illness.[36]

Case 37.—M., aged thirty-eight years, with history of attacks of intense pain in the epigastrium three or four hours after meals, without nausea or vomiting. While in usual good health, suffered an attack of violent pain in epigastrium with collapse. He recovered somewhat and then grew gradually worse, with vomiting on the third day; no movement of the bowels for a week before the attack. On the third day, temperature 100° F., pulse 99, respiration 30; face drawn; abdomen distended with gas; dull in flanks; liver dulness absent. Operation about seventy-two hours after onset of acute symptoms. Through an incision in the median line, much gas and thin greenish-yellow purulent fluid escaped with flakes of lymph; appendix normal. A search over the intestine showed the perforation to be in the anterior wall of the duodenum near the pylorus. It was sutured and the abdomen swabbed out. The operation lasted two and a half hours. One quart of saline solution was injected into the basilic vein. Death in eight hours. The peritoneal cavity was dry, except six ounces of pus between the diaphragm and liver. The suture was tight and adhesions had already formed around it.[37]

Case 38.—M., aged thirty years, with a history of dyspepsia. While stooping to draw off his boots, the patient suffered a severe pain in his stomach which stretched him out. The following day an enema was given without result. The abdomen was swollen and painful, the pain being all about the umbilicus, the urine scanty and the pulse 120. About twenty-seven hours after the accident an incision was made in the median line at the umbilicus. The intestinal coils were distended and red. A mass of fecal matter seemed to clog the lumen, and was pushed along for a couple of yards. There was a suspicious yellow fluid in the peritoneal cavity, and pus in the pelvis. The appendix was normal. The abdomen was flushed with boric acid solution and closed. The vomiting ceased, gas and a great quantity of feces passed and the abdomen became soft. Five days later the patient was attacked with dyspnea and double pneumonia developed. Death nine days after the operation. There were numerous pus foci in the abdomen, and a perforation of the duodenum partly shut in by adhesions.[38]

Case 39.—F., aged seventeen years, and fairly healthy; had rarely suffered from indigestion. One week before perforation occurred, there had been indefinite pain in the abdomen, for which she consulted a physician, who feared a beginning attack of appendicitis. About three hours after eating a hearty supper, while walking rapidly she was seized with a violent pain above the umbilicus. Prostration followed, with rapid pulse, subnormal temperature, vomiting and rigid abdominal muscles. Infusion of saline solution and stimulants failing to improve the patient's condition, operation was performed twelve hours after the beginning of the attack. Incision as for appendicitis; appendix and pelvic organs normal, as was the small intestine. In the upper part of the abdomen there was a good deal of lymph and greenish fluid. The perforation of the duodenum was in the anterior wall of its third portion and was about the size of a goose-quill, and surrounded for about an inch by an indurated area. Fluid was freely escaping. Direct sutures would not hold, so a purse-string was inserted and afterward other peritoneal sutures. In this way the opening was firmly closed. Lymph and fluid were wiped away, and the abdomen flushed with a great quantity of hot saline solution. Numerous gauze drains were inserted. Convalescence was slow, as it was a long time before the suppurating tracts, where the drains had lain for a week, had healed, but the patient ultimately recovered completely.[39]

Case 40.—M., aged thirty years; sudden pain in the abdomen followed by shock and taxis symptoms. Operation thirty-six hours later as for appendicitis. Perforation found in first portion of duodenum. No blood nor food in peritoneal cavity. Death in a few hours.[40]

Case 41.—M., aged forty years; seized with pain while at work, followed by shock and toxic symptoms and great tympanites. Operation in twenty hours. Perforation found in first portion of duodenum, no blood nor food having escaped. Death in a few hours.[41]

Case 42.—M., aged thirty-eight years. Supposed pulmonary abscess was opened and a large quantity of pus escaped. Two weeks later an abscess formed in groin and was opened. Later the abdomen was opened for appendicitis and a quart of creamy pus containing streptococci escaped. Death followed. *Autopsy:* Two ulcers near pyloric ring, one in the duodenum, the base of which had healed over, and one in the stomach—perforated. There were numerous pus-pockets in the abdomen, one in the head of the pancreas being the original one apparently.[42]

Case 43.—M., aged twenty-nine years; alcoholic. Three years' morning vomiting. Following a long spree he felt umbilical pain and vomited and had a chill. The next day the abdomen was moderately distended and rigid. Diagnosis of general peritonitis from appendicitis. Operation one to two days after attack. About one

quart of fluid and fibrin escaped. Appendix amputated. Death in thirty hours. Autopsy revealed perforation in superior anterior surface of duodenum near pylorus.[43]

Case 44.—M., aged thirty years; history of gastric disturbance; no hematemesis. Sudden severe epigastric pain, with chill, fever, and repeated vomiting and great prostration. No blood by mouth or rectum. Gradually increasing distention and tenderness. Four days later, April 30, 1900, he entered the New York Hospital, the abdomen generally swelled, but not presenting any special points of tenderness or dulness; liver dulness absent. Patient had a double hernia, and in the right hernial sac intestine was to be felt; temperature 104° F., pulse 140. Median incision with umbilicus in center. Nothing abnormal found at the internal rings or about the cecum. From a ¼ inch perforation in the antero-superior wall of the duodenum close to the pylorus brandy and water was found escaping. Closed with a double row of sutures; thorough washing of intestines and cavity; saline transfusion of seventy-five ounces, etc. Death in a few hours. Operator, Weir. Case not previously reported.

Case 45.—M., aged twenty-seven years; always healthy but a steady drinker. Had colicky pain for four days, above the umbilicus on the right side. Bowels moved daily and he kept on working. Then sudden severe pain three inches above navel and a little to right of median line; chill; no nausea. Nine hours later, pulse 80, respiration, 20, temperature 101.5° F. March 28, 1899, abdomen opened ten hours after sudden pain, along right semilunar line above and below umbilicus; bile stained fluid escaped; appendix examined as a matter of precaution and found normal. Incision extended upward to ribs. Perforation of duodenum, anterior surface descending portion, large enough to admit No. 26 F. sound, through which bile and intestinal contents were escaping. All organs in vicinity showed signs of irritation and so were washed with saline while opening was closed by pad. Suture of perforation; repeated flushing of peritoneal cavity without evisceration and wiping with dry gauze; gauze drain to ulcer; wound elsewhere closed. No shock. Patient fed by rectum for forty-eight hours. Temperature following day 101° F. and infection of skin stitches which were removed. Recovery otherwise uneventful and perfect.[44]

Case 46.—F., aged twenty-five years. Sudden attack of umbilical pain, rigor and slight vomiting. On following day pain at pylorus and blood passed per rectum. Temperature then and later 101° F. or less. Attack gradually subsided, but in two weeks a similar but slighter attack occurred. Later, a fluctuating tumor in region of gall-bladder, gradually increasing in size until it occupied the whole right upper quadrant of abdomen. It was crossed by resonant colon—elsewhere dull on percussion. Diagnosis, hydronephrosis. Through lumbar incision a quart of more of clear amber odorless fluid was drawn off. Cyst reached from liver to iliac crest and backward to spine. Kidney not felt. Stuffed with gauze, which next day was soaked with sour fluid. On third day food noticed in dressing. Patient developed acute bronchitis and died on fifth day. *Autopsy:* Duodenal perforation 3.5 inches from pylorus forming this retroperitoneal cyst below right kidney and reaching behind duodenum as far as pancreas.[45]

Case 47.—No history given. Incision from ensiform to pubis. Ulcer found at back of the duodenum and with difficulty stitched. Patient collapsed and abdominal wound hastily closed. Death from hemorrhage from a vessel in the abdominal wound.[46]

Case 48.—Patient neurasthenic and little attention was paid to his statement that he had great pain. Operation on the fifth day when liver dulness was entirely obscured. Gas had escaped from the perforation, but no fecal matter, and the ulcer was therefore sutured and the abdominal wound closed without drainage. Death on the third from infection leading from the site of perforation to the pelvis. Suture firm. The operator thought that pelvic drainage might have saved this patient.[47]

Case 49.—M., aged fifty-two years. Epigastric pain of three days' duration was followed by violent exacerbation. No vomiting. Six hours later the abdomen was tense, rigid, almost motionless, with complete absence of liver dulness in the line of the nipples. A diagnosis of perforated duodenal ulcer was made and operation decided upon. Ten hours after the attack an incision was made through the right rectus and a clean-cut perforation found at the junction of the first and second portions of the duodenum. There was intestinal injection but no well-marked peritonitis. The perforation was closed with two rows of sutures, the intestines were brought out and washed with sterile water. A gauze slip was passed to the site of ulceration and the cavity of the abdomen was otherwise closed. Recovery uneventful. The gauze plug was removed on the second day, and the bowels moved on the third day.[48]

Case 50.—M., aged twenty years. Seven months previous an attack of epigastric pain and vomiting lasting two weeks. Sudden severe pain in the right side of the abdomen, accompanied by vomiting. A few hours later the tenderness was greatest over the appendix. Temperature 102° F., respiration 48, pulse 118. Diagnosis, appendicitis. Twenty hours after the attack, an incision over the appendix allowed the escape of a quantity of odorless gas and fluid. On account of feeble condition further operative attempt abandoned. Death in twenty-four hours. *Autopsy:* Perforation in the duodenum, anterior wall, just beyond the pylorus.[49]

Case 51.—M., aged forty-five years, a moderate drinker. Four years previous had a similar attack. While in perfect health was seized with severe pain in the right side of the abdomen, referred to the iliac region. A few hours later the

abdominal wall was tense, without distention, or loss of liver dulness; tenderness over the appendix; temperature 100° F., respiration 32, pulse 104. Diagnosis, appendicitis. Twenty-two hours after the attack an incision over the appendix evacuated considerable turbid serum. The appendix was normal. The peritonitis was most marked on the right side and was followed up the colon to the hepatic region, but no cause for it could be found. The whole abdomen was flushed and drains were placed in the duodenal region and in the pelvis. Death in seven days. Autopsy showed a general exudative peritonitis, without free fluid. In the duodenum, anterior wall, just below the pylorus, was a perforated ulcer, and the scar of a healed one.[59]

Association of American Physicians.—The following officers for the ensuing year were elected at Washington, D. C., May 3, 1900: President, Dr. William H. Welch, of Baltimore; vice-president, Dr. Henry P. Walcott, of Cambridge, Mass.; secretary, Dr. Henry Hun, of Albany, N. Y.; treasurer, Dr. J. T. Crozier-Griffith, of Philadelphia, Pa.; recorder, Dr. I. Minis Hays, of Philadelphia, Pa.; member of the council, Dr. William W. Johnston, of Washington, D. C.

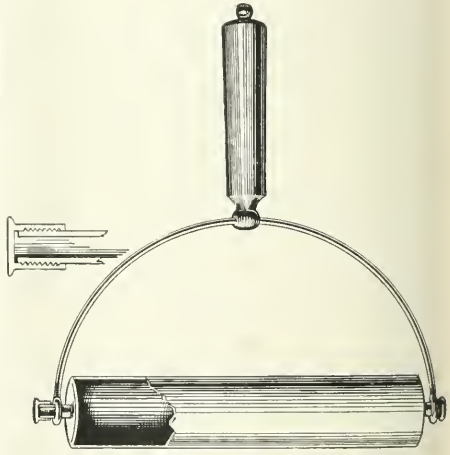
CLINICAL MEMORANDUM.

A METAL ROLLER WATER TANK FOR THE APPLICATION OF HEAT OR COLD (COUNTERIRRITATION).

By ROBERT COLEMAN KEMP, M.D.,
OF NEW YORK;
CLINICAL ASSISTANT TO THE CHAIR OF SURGERY IN THE NEW YORK POLYCLINIC MEDICAL SCHOOL AND HOSPITAL.

The various methods for the application of heat for purposes of counterirritation, such as by the Paquelin cautery, the hot-water bag, or ironing with the flatiron or small gas iron, are familiar to us all. The cautery can only be employed by a physician and is objected to by nervous patients. The hot-water bag is heavy and the heat necessarily is continuous, not intermittent and the degree hard to regulate; while with the ironing, the weight of the iron and the difficulty of passing it rapidly and smoothly over the surface without blistering are the objectionable features; nor can it always be conveniently secured. We present to you in Fig. 1, which was

Fig. 1.



Roller Water Tank.

drawn for me by Mr. Thomas Nast, Jr., a device which possesses the merits of simplicity, lightness, cleanliness and cheapness, and which has demonstrated its value by practical use.

It consists of a closed metal cylinder, three and one-half inches long and one and one-third inches in diameter. The walls are extremely thin, so as to secure good conduction. In order to obtain maximum space for the water, the axles for rotation are placed at the ends of the cylinder and soldered there, thus avoiding a single axle which would necessarily be passed through a central tube and give less space for fluid. One of these axles is a hollow tube and through this the cylin-

der is filled with water. The screw-thread is outside this tube and the cap-screws over and around it, as shown in the smaller diagram. The washer is a solid disc at the bottom of the cap and can be readily replaced by cutting and fitting a small piece of leather. Some difficulty was experienced in expelling the air from the cylinder when filling it, even with a funnel. To obviate this the tube is beveled on the inside in several places, making small gutters for the escape of air about the funnel, even when water is poured directly in. This is feasible, since the hollow filling-tube has the screw-threads and cap on the outside. We find that making the filling-tube slightly funnel-shaped on the outer end is not as practical. An air-vent at the end of the instrument next to the filling-tube, with a screw-cap to close it after the escape of air, is more complicated and costly. The use of a glass roller is somewhat objectionable on account of the expense, liability of breaking, through heat or rough handling; the cork is liable to slip out, under the rapid rotation, and the glass is often rough and heavy—the latter to secure durability—and, moreover, the axles are liable to break.

The illustration readily explains the action of the roller. It is made of brass nickel plated or of gun-metal, and each is supplied with a small metal funnel for filling. The method of application is as follows: It has been my custom to fill the roller with boiling water to about half its capacity, and have more boiling water, or preferably a little alcohol boiling apparatus in action at hand, and change the fluid when it cools. By practical experience the instrument remains sufficiently hot for about five minutes, and then the water is renewed instantaneously, as just described. About two applications or, if required, more can be easily given. A thin handkerchief is first placed over the part, and this can be shortly removed, as the metal cools. The degree of heat can also be regulated by the rapidity of movement and the amount of pressure. If necessary, it can be merely skimmed over the surface.

If cold is to be employed, ice water is readily obtained, or cold water. A little pulverized ice and salt can be added. The patient can easily be instructed in its use.

The applications of this instrument readily suggest themselves, as for instance, in sciatica, muscular rheumatism, neuritis, rheumatic joints, etc. Ointments made with lanolin can be rubbed in, protecting the instrument, the heat being of value to promote absorption.

If moist heat is desired, the handkerchief or flannel can be wrung out in hot or cold water and placed over the part and the cylinder rolled over it. The roller can be made small or large, but the standard dimensions noted are convenient. For skin work a smaller size can be ordered to suit. The instrument is cheap and can be secured, with the funnel for filling it, at the cost of $1.00 at the instrument-store of James T. Dougherty, 409 and 411 West Fifty-Ninth Street. We are aware that there are electric and massage rollers, but so far have no knowledge of the simple device above described.

Ichthoform.—S. Rabow and B. Galli-Valerio (*Therap. Monatshft.*, April, 1900) have made an extensive experimental study of ichthoform, a combination of ichthyol and formalin, which leads them to the following conclusions: (1) Ichthoform when added to cultures has no power of directly killing bacteria, although it restrains their development. (2) It possesses a decided deodorizing power when mixed with fecal matter. (3) Neither frogs nor guinea-pigs react unfavorably to even large doses. (4) It can replace iodoform externally and internally is an efficient intestinal antiseptic.

Resoldol.—The value of the condensation product of saloform and resorcine which has recently been recommended as an intestinal tonic and astringent is stated by Herrmann (*Therap. Monatshft.*, April, 1900) as follows: (1) Being insoluble in water and acids and freely soluble in alkalies, it is probably split up in the small intestines into salicylic acid and resorcine. Saliva and diluted bile readily dissolve it, while in the gastric juice it merely remains suspended. (2) Experiments with the hanging-drop gave materially diminished motility of typhoid and colon bacilli. (3) It is relatively harmless and even large doses may be given with impunity. (4) The taste is but slightly astringent and not disagreeable, and the difficulty sometimes experienced in swallowing the drug can readily be obviated by administering it in wafers. (5) No eructations or other gastric symptoms are complained of and its rectal use is equally convenient and safe. (6) A reduction of temperature could not be demonstrated, nor could salicylic acid or resorcine be detected in the urine. Clinically the author has found resoldol valueless in irritative or purely neurotic diarrhea, but has had more success in those cases depending on infections. Enterocolitis, chronic colitis and intestinal tuberculosis yielded in a remarkable way, while with typhoid the results have not been sufficiently gratifying to pronounce the drug a specific. In cases with marked indicanuria due to coprostasis a decided reduction of the indican was obtained without emptying the bowels. Lastly, resoldol was found to prevent the fetid odor of alcoholic stool. The recommended dose is 45 to 75 grains daily.

Leucocytosis in Surgical Cases.—J. C. Hubbard (*Bost. Med.-Surg. Jour.*, April 19, 1900), after reviewing all the surgical cases in the Massachusetts General Hospital during the last five years, in which white blood-cell counts were made, comes to the following conclusions: The count in health, in non-purulent inflammatory conditions, in purulent conditions, and in non-inflammatory lesions, varies between wide limits. The limits of variation are so nearly alike in these various conditions that the count gives assistance neither in diagnosis nor in prognosis.

SPECIAL ARTICLE.

THE JACOBI CELEBRATION.

A. Jacobi, M.D., LL.D.,
May 6, 1900.

The seventieth anniversary of the birth of Dr. A. Jacobi was celebrated at a banquet held Saturday evening, May 5th, at Delmonico's, New York City, and was attended by more than four hundred friends and professional associates of the guest of honor. The gathering included many of the leading medical men of the country, some of whom came from as far as the Pacific Coast to take part in the commemoration. Among those who attended the banquet to mark their appreciation not only of Dr. Jacobi's high attainments as a physician, but of those personal qualities which have gained for him so many friends on both sides of the Atlantic, were men whose names are prominent in commerce, finance and the professions.

Dr. Joseph D. Bryant acted as toastmaster, and seated with him at the guest table, in addition to Dr. Jacobi, were Seth Low, President of Columbia University; Dr. John S. Billings, Dr. William Osler, of Johns Hopkins University; Carl Schurz, Dr. W. H. Thomson, President of the Academy of Medicine; Dr. Charles S. Fairchild, John S. Kennedy, Dr. W. M. Polk, D. S. Lamont, J. W. Keller, Commissioner of Charities; Joseph Larocque, Dr. T. M. Rotch, of Boston; Dr. W. H. Welch, of Baltimore; Professor Chandler, of Columbia; Dr. James W. McLane and Horace White. A large number of women listened to the speeches from the gallery, among them being Mrs. Mary Putnam Jacobi, wife of the guest of honor.

The after-dinner part of the ceremonies was opened by Dr. Joseph D. Bryant, late President of the Academy of Medicine, who presided. He spoke briefly of Dr. Jacobi's career and of his contributions to science:

The reasons for our presence here this evening require of your presiding officer no special words of explanation. Every participant in the spirit of the occasion within this spacious hall, and many without, whose presence we are denied, fully comprehend the significance of the event.

How fortunate indeed it is, in the affairs of this life, that worthy and well-directed efforts, addressed to securing personal and public betterment, frequently beget, though ofttimes somewhat tardily, the sentiments of abiding confidence and esteem for those who prudently proclaim their importance, and diligently labor for their attainment. The opportunities for achievements of this nature are everywhere present and so conspicuously clothed as to invite prompt recognition.

The declaration of the fact that he whom we now honor has throughout his career proven a vigilant and effective exponent of scientific advance and of public excellence suggests no denial and venerates the occasion. I believe, however, that it should be recognized at the outset that the observances of the evening are not devoted more to the learned gentleman, whom we so much delight to honor, than to the recognition of those ennobling virtues of which he is the embodiment, and which, when practised with faithful exactness, make of us better men, better citizens, and therefore establish a better world.

The notable examples of the beneficent labors of our esteemed friend in the exercise of his professional skill and fraternal devotion are singularly akin to each other in their inception and in their spirit. In the one example he dedicated, through various channels of bounty, the full measure of his professional sagacity and fervor to the alleviation and cure of the suffering incident to the freedom of individual birth. In the other we are taught by the history of his fatherland that he bestowed a like measure of patriotic zeal to liberty's cause, fostering the birth of individual freedom. To the former service the ripe abundance of his years has been given, to the latter the richness of his youth was well-nigh sacrificed; with both, his name is indelibly recorded as the wise physician and the uncompromising patriot. Numberless hapless poor of the common sphere of life mingle their joy with that of those of higher station, in acknowledgment of the bountiful aid and comfort experienced at his hands.

Medical thought and medical progress, here and abroad, bear abundant evidence of the potent influence on their status of the products of his studious, logical mind. Thousands of physicians, while students in medicine and at bedside consultation, have gained inspiration and comfort from his teachings and advice in a degree equaled only by that of the fortunate recipients of his pro-

fessional ministrations. All along the avenues of commendable professional endeavor directed to the attainment of proper public recognition, of increased knowledge and *csprit,* are noted exalted products to the achievement of which he contributed an untiring energy, guided at all times by sincere executive thought. The justice of this statement is witnessed by the significant presence of the New York Academy of Medicine and its library, and further emphasized by the fact that, in the late effort to increase the latter, he supplemented a previous bountiful contribution by the major part of the recent gain.

The patriotic zeal of his earlier life was an earnest of his devotion to public duty during the latter, and in neither instance has the cry of distress gone unheeded, while in both the weak have been strengthened, the wavering encouraged, and the justice of a cause assured by his word and presence. What he was to those of noble aspirations of the land of his birth, he has been and is to those of the land of his adoption.

Such as this, my friends, is something of the record of him whom we honor this evening, more of which, however, will be told by those whose coöperative experience and comradeship permit of more complete and profound utterance than my opportunity or knowledge affords.

I am prompted, however, to say to Dr. Abraham Jacobi himself: Though thy years be three score and ten and each replete with a glorious harvest, so well hast thou performed thy useful missions that we do hope and pray that life's Scriptural allotment of time may be long extended for you, that not only the example for good shall remain, but good itself be correspondingly multiplied.

Numerous letters and telegrams from well-known scientists and physicians from all parts of the world were read, and an original poem by Dr. S. Weir Mitchell of Philadelphia, laudatory to Dr. Jacobi's life and his achievements, in the absence of Dr. Mitchell, was read by Robert Underwood Johnson.

No honors hath the State for you whose life
From youth to age has known one single end.
Take from our lips two well won titles now,
Magister et Amicus—Master, Friend.

From the gray summit of attainment you
Look on the rugged path you knew to climb.
Take, with our thanks, for high example set
The palm of honor in this festal time.

Constant and brave, in no ignoble cause
The hopes of freedom armed thy sturdy youth:
As true and brave in these maturer years
Thy ardent struggle in the cause of truth.

Nor prison bars, nor yet the lonely cell,
Could break thy vigor of unconquered will:
And the gray years which build us cruel walls
Have found and left thee ever victor still.

Ave Magister! Take from us to-night
The well-earned praise of all who love our art
For this long lesson of unending work,
For strength of brain, and precious wealth of heart.
Your busy hand gives much; but, oh, far more,
The gallant soul that teaches how to meet
Unfriended exile, sorrow, want and all
That crush the weak with failure and defeat.

We gave you here a home; you well have paid
With many gifts proud freedom's generous hand
That bade you largely breathe a freer air,
And made you welcome to a freer land.

Ave Amicus! If around this board
Are they who watched you thro' laborious years.
Beyond these walls, in many a grateful home,
Your step dismissed a thousand pallid fears.

That kindly face, that gravely tender look,
Thro' darkened hours how many a mother knew!
And in that look won sweet reprieve of hope,
Sure that all earth could give was there with you.

Ave Magister! Many be the years
That lie before thee, thronged with busy hours!
Ave Amicus! Take our earnest prayer
That all their ways fair fortune strew with flowers.

Dr. William H. Thomson was then introduced to speak of Dr. Jacobi as a physician. He reviewed the venerable physician's services to the science and practice of medicine, and was followed by Dr. William Osler of Johns Hopkins University, who spoke on "Dr. Jacobi as a Man of Science:

Gibbon very wisely says that the only one person capable of passing a correct judgment upon the works of an individual is the author himself. Who knows so well as he the merit of the performance; who so interested in them? Fully agreeing, as every author should, with this authoritative statement, I must begin with an apology to Dr. Jacobi for an attempt to usurp his function, but under the circumstances he will forgive me.

A first and most surprising impression in a review of our friend's literary work is its very modest amount—only three or four volumes, and some sixty major monographs and essays. Knowing the encyclopedic character of the man, how commendable seems this moderation! The first publication against his name is the Bonn Thesis, 1851, *"Cogitationes de vita rerum naturalium."* I doubt if Dr. Jacobi could now appreciate the Cogitationes. The thesis, which is modest only in size, has all the dogmatic freshness of the production of a youth of one-and-twenty. The conclusion of the whole matter is given in a few brief lines at the close: *Nil extra naturam, nil extra matcriæ leges,* and there is a third and concluding phrase which I refrain from quoting. It is interesting to note so early in his career the influence of the great master, Rudolph Virchow, from whose writings several quotations are given. With one phrase I remember to have been caught years ago: *"Die Wissenschaften und der Glaube schliessen sich aus."* Science and faith have nothing to do with one another, and only worry comes from a neglect of that strong statement by Tennyson of their essential divergence:

"We have but Faith; we cannot know;
For Knowledge is of things we see."

Then comes the most impressive period in our author's life—silence for seven or eight years, during which I can find in indexes and catalogues nothing against either his name or his reputation. It is unique, almost, in the literary history of our profession. Would that this more than Pythagorean period of self-restraint could be emulated to-day! But think of the desolation to editors if all the graduates of all the schools of all these States thought and worked, but did not write for seven years after their graduation!

In this audience it seems almost superfluous to speak of the professional writings of Dr. Jacobi. Of his larger works the "Diphtheria" monograph and the "Treatise on the Therapeutics of Infancy and Childhood" have been guides and counselors to thousands of physicians all over the land. Nowhere has there been a better student of diphtheria or a sounder exponent of the subject than Abraham Jacobi. One of his earliest works, the contributions in connection with Dr. Noeggerath, I could not find. Dr. Jacobi mentioned the other night in Washington that it had cost them about a thousand dollars to publish them. I understand that it has disappeared absolutely. It is not known whether Dr. Jacobi possesses copies, nor is it known how much it cost the authors to buy up the entire edition, which is the only possible explanation of its rarity.

Of the monographs and special articles I should like to speak at length were there time, particularly of the splendid contributions upon the intestinal disorders of children. The monograph on the Thymus Gland is a model of careful research. You know as well as I of his scholarly and sound contributions in the various systems of medicine which have appeared from time to time. Of the many occasional addresses that entitled *Non Nocere,* before the International Congress at Rome, and the appreciative sketch of Virchow are models of their kind. I was much interested in one well-worn booklet in the Surgeon-General's Library—the earliest of his contributions in the collection of 1860 or 1861—in which a series of cases is narrated, and in which he gives a statement of how to teach the subject of pediatrics in practical classes in the dispensaries. In this he was, I believe, a pioneer in the United States.

I come now to what may be considered the most important part of his life's work, that relating to infant-feeding. It may be said that the safety of a nation depends on the care of its infants, and no one in this country has done so much for their bodily welfare as Dr. Jacobi. Had they any other language but a cry countless thousands of colic-stricken babes and sucklings would ordain great praise to him this evening. For more than thirty years we find this problem engaging his closest attention, and he has never tired of urging proper methods upon the profession and the public, methods which have always been characterized by his strong, clear sense. There is no single question before this nation-to-day of greater importance than how to return to natural methods in the nature of infants, and you will pardon me if I here make a slight digression. The neglect of the natural mode is an old story in Anglo-Saxondom. St. Augustine, so Bede tells us, wrote to Pope Gregory complaining that the question of infant-feeding was worrying him not a little. I understand that a systematic effort is to be made to supply to every child born in this land its rightful sustenance for one year at least. Under the auspices of the Pediatric Society and the Woman's Christian Temperance Union, a Woman's Infant-Suckling Union is to be established which will strive to make it a criminal offence against the State to bottle-feed any infant, and which will provide in large and well-equipped sucklingries ample sustenance when a mother from any cause is unable to do her duty. Rotch tells me that the action on the part of the Pediatric Society has been influenced by an exhaustive collective investigation on the future of bottle-fed babies, in which it is clearly shown that intellectual obliquity, moral perversion and special crankiness of all kinds result directly from the early warp given to the mind of the child by the gross and unworthy deception to which it is subjected —a deception which extends through many months of the most plastic period of its life. According to these researches you can tell a bottle-fed man at a glance, or rather at a touch. *Feel the tip of his nose.* In all sucklings the physical effects of breast pressure on the nose are not alone evidenced in the manner set forth so graphically by Mr. Shandy, but in addition the two cartilages are kept separate and do not join, whereas in bottle-fed babies, in whom there is no pressure on the tip of the nose, these structures rapidly unite, and in the adult present to the finger a single sharp outline, entirely different from the split, bifid condition in the breast-fed child. The collective investigation demonstrates that all silver democrats, many populists and the cranks of all descriptions have been bottle-fed, and show the characteristic nose tip. Utopian as the scheme may appear (and directly suggested, of course, by Plato), who can question the enormous benefits which would follow the substitution of such sucklingries for the present Walker-Gordon Laboratories and other devices —benefits untold to helpless infants; blessings to thousands upon thousands of women whose energies would be directed into their natural lactiferous channels, and, most important still, a gradual elimination of those pernicious bottle-fed influences, to which may be attributed so many evils both to the State and to the individual.

Looking over Dr. Jacobi's books and papers, one gets the impression of an honesty of purpose and a sincerity in them all. There is no claptrap, no gallery-play, but a faithful administration of an intellectual trust, and, what is more,

the professional spirit is reflected in them always on the nobler side. There is a double meaning in the well-known lines:

> "Heard melodies are sweet, but those unheard
> Are sweeter."

and let us hope that what may come from his pen in the future may excell his past performances. A volume of poems, "*Songs in Silence*," written *in der stille* of his prison-house, would be most acceptable, or a novel (of which Dr. Janeway has just spoken to me) in three volumes, or, better than either, his "Jugenderinnerungen," which he really should leave to us as an evening legacy.

To speak seriously, this magnificent demonstration is a tribute not less to Dr. Jacobi's personal worth than to the uniform and consistent character of his professional career. The things which *should* do not always accompany old age. The honor, love, obedience and troops of friends are not for all of us as the shadows lengthen. Too many, unfortunately, find themselves at seventy "nursing a dwindling faculty of joy," amid an alien generation. Fed on other intellectual food, trained by other rules than those in vogue, they are too often, as Matthew Arnold describes Empedocles, "in ceaseless opposition." Against this interstitial decay, which insidiously, with no pace perceived, steals over us, there is but one antiseptic, one protection, the cultivation and retention of a sense of professional responsibility. Happiness at threescore years and ten is for the man who has learned to adjust his mental processes to the changing conditions of the time. In all of us senility begins at forty—forty sharp—sometimes earlier. To obviate the inevitable tendency, a tendency which ends in intellectual staleness as surely as in bodily weakness, a man must not live in his own generation. He must keep fresh by keeping in contact with fresh young minds, and ever retain a keen receptiveness to the ideas of those who follow him. Our dear friend has fortunately been able to do this in a remarkable manner, since he is one

> "Whose even-balanced soul
> Business could not make dull, nor passion wild,
> Who saw life steadily and saw it whole."

Mr. Carl Schurz, speaking upon the theme of "Dr. Jacobi as a Citizen," said in part:

"In him we see one of the adopted citizens whose peculiar patriotism is not always quite understood and appreciated by our native friends. It may strike some of you as somewhat audacious when I say that the adopted citizen may in a certain sense be a more jealously patriotic American than the native. And yet it is true. The adopted citizen usually preserves certain sentiments and reverential attachment to the country of his birth. But just because of this, many of them are especially anxious to see the country of their adoption by its virtue and the high character of its achievements justify their separation from their native land, and enable them to point with just pride to the choice they have made. They may for this very reason, when they see the character of their adopted country put in jeopardy, or its good name in the family of nations endangered, resent this, and stand up for the cause of right, and of integrity, and of honor in their adopted country with an intensity of feeling even greater than that which ordinarily animates the native."

Then came the presentation of the "Festschrift." Dr. A. G. Gerster was deputed to hand the volume to Dr. Jacobi, and in doing so he said: "It was nearly two thousand years ago that the poet of the Augustine era, Horace, penned the boastful but true words, 'Exigi monumentum ære perennius.' Everyone knows how the prediction has been literally fulfilled. However, the poet's conviction would not have been thus confidently expressed had there not been underlying it the solid fact that of all men's works there is none more enduring than the written word. It is not strange, therefore, that when a group of five men met a year ago last February to consider a way in which the seventieth birthday of Dr. Jacobi ought to be celebrated, that the idea of publishing a 'Festschrift,' that is, a collection of literary contributions furnished by a number of willing friends and colleagues, was immediately adopted.

"I hold in my hand a volume containing the scientific contributions of fifty-three medical men of note, men representing two continents and eleven nations. This tribute of the veneration and esteem of the authors is adorned by a splendid etching, the product of the masterly needle of James D. Smillie, a faithful image of the Ambrosian features of the original. I trust that the contents of the volume may be found as worthy of him whom they are meant to honor as their outward garb."

Dr. Jacobi, rising to respond, was greeted with cheers that were again and again renewed. He was obviously moved by the warmth of the reception extended to him, and in beginning his address he expressed the wish that he could proceed from man to man and in silence press their hands, for words did not suffice for the throng of feelings that swelled his heart.

When he first came to this country, he said, he knew nothing of American medicine. It was simply unknown in Europe. Nor was America much better informed in regard to European medicine. With the exception of a few translations from the French and a number of English republications—called American editions—European literature was but scantily known and appreciated, except by the few. He reviewed the progress and development of medical education and institutions in this country in the period over which his knowledge extended. Continuing, Dr. Jacobi said:

"I take it for granted that I am expected to speak, in part, I suppose, of the topic of the evening—myself. But how? And what? I have been eulogized as if I were dead. Not being quite

dead yet, I should not join in the praise. On the other hand, to speak derogatorily of my doings would be discourteous to those who expressed their good opinions.

"In accordance with my democratic schooling, I was fortunate enough to have respect for the individual. That is why I found it easy to imagine myself in the place of a patient and to spare his feelings if I could not preserve his life. Where you cannot save you can still comfort. I never told a patient he had to die of his illness, and I hope I shall never be so careless or so indolent as to do so in future. The magnetic needle of professional rectitude should, in spite of occasional deviations, always point in the direction of pity and humanity. Another lesson I learned early was this, that my patient had to be treated, and not the name of his disease.

"Meanwhile the profession, and I among them, has plodded on. Untold thousands have arisen this half century of mine, or passed away. There were the wage-workers, the teachers, the pathfinders. There were those who fought disease or epidemics bravely and survived, or those who died in a single task and left their small children hungry. It is true the time has passed by when the doctor was killed when he lost a patient. That is different now. We are more civilized. We are satisfied with murdering his good name.

"The brave physician's work was always hard, for it is as difficult to save one life as it is easy to kill a thousand. That is why I cannot feel enthusiasm for the doctor who is occasionally puffed for leaving his humane work to participate in the killing; nor for the injustice of history that mentions a thousand generals to one physician. Some of what I have said may be objected to. But I know that the views I expressed were mine always, and are not engendered by advancing age. What, after all, is age? The boundary line between the young and the old is not, I take it, in the bald head or the gray whiskers, but in the change of a man's ambitions, motives and purposes, and of his relations to the world and its ways and aims. It is true I have been told even to-night that I am seventy, in the pleasant way, though, you have of showing your condolence. I can bear it as long as those not so old as I am accused of being treat me as their equal and call me young—for an aged man.

"A word to the young. I am afraid we old men are past changing; but it is a failing in our national character to be always cordial, always courteous, always handshaking. We do not identify the sin and the sinner; we abhor the former, and are too good-natured to shun the latter. If there be a danger to our morals and our politics, it is there. If you, the young men in the profession, will refuse approval and honors to men whose actions and methods you condemn; if you will only show them that your heart is chilled against them—some of them are in public positions—there will soon be an end to offences which need not always result from wickedness, but bad taste only. There are those indeed among the vain who fear the display of bad taste more than the perpetration of sin.

"After all, however, when I look backward I really do not believe that the moral tone of the profession is lower than circumstances will always necessitate in this period where trade is everything. There was jealousy, strife, and competition at all times, and men were always human. The 'good old times' is an ideal that, while its consummation is too far ahead or beyond the horizon altogether, is searched for backward. Doctors were always what their time, their people, their surroundings made them.

"And this 'Festschrift!' These last weeks I wondered many a time, and I do so now, that I should be the receiver of that honor. When many years ago heroes like Virchow and then, again, Henoch, were to be held up for the admiration of the medical world, on both occasions I had the privilege of coöperating in the expression of the estimation in which they were held. This distinction is rare even in the country of my birth.

"That the country which adopted me and made me a peer among peers, opportunities to work, should in true cosmopolitan spirit adopt this method, rare enough in Germany, of raising a man to the greatest possible height of distinction and make him shine above all men—and this man I—is far, far beyond what was the culmination of all my possible hopes."

By the calendar the anniversary of Dr. Jacobi's birth fell upon May 6th, and although the dinner was begun the previous night, it was continued well into the early hours of the guest's natal day. At midnight the four hundred and more diners rose in a body and with filled glasses drank, to the accompaniment of song and cheers, a toast of long life and happiness to Dr. Jacobi.

The Festschrift is in the form of a volume of some five hundred pages, and is entitled "International Contributions to Medical Literature." It contains a symposium on medical subjects by a large number of French, German, English and Spanish scientists. Nearly a year was required to compile the work, which was planned after those presented to famous European scientists upon their anniversary. It is believed to be the first of its kind ever prepared in this country, and an edition of a thousand copies has been printed for distribution among the libraries and physicians of the United States.

MEDICAL PROGRESS.

Fortoin—A New Cotoin Preparation.—Overlach (*Wiener medizin. Blaetter*, April 12, 1900) reports on the value in therapeutics of the new preparation of cotoin produced by the action of formaldehyd on the latter and called fortoin. It is a yellow, crystalline substance, with an odor suggesting cinnamon, and tasteless. The dose of fortoin is 0.25 gram for adults three times daily. As much as 0.5 gram can, however, be borne

without any disturbances arising. Its chief indication is the diarrhea arising from any cause in which the intestinal mucous membrane has been dislodged in places and carried off. Heretofore the tannin preparations have been used in such cases, but the disorder always returned with the discontinuation of the drug, for tannin does not cause regeneration of the membrane to take place. On the other hand, fortoin stimulates the membrane to renewed growth and activity, resulting in the rapid return to its normal condition in which proper resorption may again take place. Overlach has used fortoin in eight cases of typhus abdominalis of which five were indubitably benefited. Hemorrhage did not result in any of the cases. Fortoin seems to be a drug of considerable efficiency.

The Hair and Severe Fevers.—G. T. Jackson *N. Y. Med. Jour.*, May 5, 1900) gives several very useful hints in regard to the management of entangled and loose hair after severe illness. An attempt should be made to have the hair combed or brushed each day during the illness, and in this way bad snarls may be avoided. If, however, the patient recovers with a mass of entangled hair and is under fifteen years of age the hair may be cut, but after that age and even below it, if the patient can command good attendance, it is much preferable to have patience and disentangle the hair by quiet and persevering effort. He advises against shaving, as it entails a great deal of discomfort from wearing a wig and causes a good deal of useless embarrassment. Only the diseased hair is removed by daily combing. Once or twice per week a little pomade, containing a dram of precipitated sulphur to the ounce of cold cream, should be well rubbed into the scalp, or a three-per-cent. resorcin solution in alcohol and oil may be used. Once in two or three weeks a shampoo with any good soap, such as the tincture of green soap, should be given. After washing, the hair should be carefully dried and a little pomade rubbed into the scalp to take the place of the natural oil removed.

Guajacetin in Tuberculosis.—The most extraordinarily favorable results have been obtained by W. Meitner with guajacetin in tuberculous cases (*Wien. klin. Rundschau*, April 1st, 1900). The special points of preference are the prompt cessation of temperature, the lessening of the mucous secretion and the good influence upon the night sweats. Guajacetin differs from other remedies in that it has no effect upon the accessory organs. Indeed, upon the stomach it exerts even a beneficial influence, acting as an admirable stomachic. It is often of great advantage to combine encasin with this drug, especially in the old cases with intense gastritis.

Ichthalbin in Intestinal Affections.—From a study of a large number of cases suffering from catarrhal affections of the alimentary tract, B. Rolloy (*Münch. med. Woch.*, April 24, 1900) reaches the following conclusions: (1) Ichthalbin in maximum doses of 2 drams daily can be taken continuously without causing constipation or irritation of the gut or kidneys. (2) It diminishes the excretion of nitrogen and thus allows of better proteid assimilation. (3) An increase in appetite and gain in weight are among its good results. (4) Abnormal putrefaction in the intestine is regularly diminished. (5) In simple chronic enteritis, as well as in cases complicated with chronic peritonitis or tuberculosis, good results are almost uniformly noticed. (6) Even subacute gastric and intestinal inflammations are favorably influenced. The proper dose is 5-10 grains three times daily for children under one year, and 10-15 grains for those over one year of age.

Treatment of Consumptive Poor.—It is, of course, almost always advisable to send those unfortunates who are afflicted with early pulmonary tuberculosis away from a city like New York and into a suitable climate amid pleasant and healthful surroundings. Among the poor, however, there are always numerous cases that are practically unable to afford such luxury, and it is, indeed, a problem to know how to manage such patients. J. F. Russell (*N. Y. Med. Jour.*, May 5, 1900) has detailed a plan which has been followed at the Post-Graduate Dispensary during the past two years with a moderate degree of success. The experiments were tried on those cases which showed unmistakable signs of tuberculosis and yet had not gone on to the formation of cavities or the involvement of large areas of the lung. All the patients were employed during the day, but were required to come to the dispensary twice each day, early in the morning, and in the evening. The plan of treatment followed was based on what is generally accepted as the most rational one, *viz.*, fresh air and sunlight in abundance, good food, plenty of sleep, regulated exercise and attention to the small things of daily life which are known to influence nutrition favorably. The instructions given included the injunctions that they must present themselves at the dispensary twice each day, Sundays and holidays included; that they must eat regularly the most nutritious foods within their means, alcohol being forbidden and tea and coffee limited; that they must keep their feet dry and warm and avoid overclothing; that they must sleep with windows open in all weather, and must keep in the open air as much as possible, avoiding places of amusement and late hours at night. No medicines were given except cathartics, but at each visit any change in the patient's condition could be noted and carefully attended to. A preparation of easily digested fats was also given at each visit to aid in the nutrition of the patient. By this means a large number of poor people suffering from pulmonary tuberculosis in a curable condition can be reached and successfully treated without interfering with their means of livelihood.

Bromipin in Epilepsy.—In an article by A. Kothe in the *Neurol. Centralbl.* is reported in the

Wiener mediz. Blätter (April 12, 1900) in which the author outlines the treatment of epilepsy with bromipin. Every case, whether of recent origin or not, is compelled to submit to absolute rest in bed for some weeks at first. This rest is disturbed only by two weekly baths in tepid water; the diet being hygienic-dietetic in character. No medication is resorted to at all at the beginning of the treatment. After the lapse of several weeks and at the termination of a severe attack the bromipin treatment is begun. The initial dose is about 15 grams, introduced per rectum and increased within six or seven weeks to 30 grams or even 40 grams, but never is a larger dose given than will just suffice to control the tendency to convulsions and the possible psychic disturbances. At that point the treatment remains for about two or three weeks, and then a gradual diminution in the administration of the bromipin to the original dose, is advised. The entire course of treatment occupies about a quarter of a year. Occasionally it is necessary to repeat the course once or twice, but in these repetitions it is not advisable to include the rest in bed. Whether the good results obtained by this treatment are due to the different methods of administering the bromipin or whether they are due to the different combination of the bromine remains to be seen. The chief value of any treatment for grand mal lies, in the author's opinion, in the strict regulation and method of the treatment and in the prolonged course during which such treatment is applied.

The Bubonic Plague.—Walter Wyman, Surgeon-General Marine Hospital Service, says (*Document 2165, Treasury Dept.,* Washington, 1900) that the plague or malignant polyadenitis is caused by a coccobacillus, devoid of automobility, and best stained by a one-per-cent. carbolized solution of thionin. In persons recently dead of the disease it takes the form of a long slender, segmented, and vacuolated bacillus. It is carried about by rats, mice, snakes, beetles, bugs, flies, dogs and other animals which are susceptible to the infection, but not by the purely herbivorous animals such as horses, sheep, rabbits, etc. In many instances an excessive mortality among rats has been noticed previous to the outbreak among human beings, those being first infected who had handled the dead rats. The bacillus enters the body through a wound, or the air passages, or the alimentary tract. Its development is favored by heat and moisture, bad sanitary conditions, and insufficient food. The death-rate among Asiatics is from 50 to 90 per cent., but among Europeans is less than 20 per cent. The disease can be easily controlled by careful isolation and sanitation, one of the best disinfectants for rooms being formaldehyd gas. All evacuations, sputum, clothing, bedding, etc., should be disinfected, and the patient kept isolated for one month after apparent recovery. Among those attendant on the sick, one c.c. of the Haffkine prophylactic should be injected once a month. The viability of the plague outside the animal body is very short, and it is probable that merchandise is not an important factor in spreading the infection. The period of incubation varies from twelve hours to eleven days. The disease has been classified clinically into the bubonic or ganglionic, the septicemic, and the pneumonic forms. Usually a small red spot marks the point of infection, and this becomes vesicular, and then pustular, and in the bubonic form a general redness, or a series of vesicles, may mark the passage of the infection along a lymphatic channel. The bubonic form begins with a chill, fever, much prostration, nausea, vomiting, pains in the head and limbs, and the rapid formation of a painful bubo surrounded by extensive edema. The glands of the groin, axilla and neck are most susceptible. If these break down and a general infection takes place the patient becomes rapidly septicemic, with stupor, delirium, and cardiac weakness. If the swelling is limited and an abscess forms, there is a marked amelioration of the symptoms and the prognosis is favorable unless secondary infection takes place. The bubonic form may be so mild as to go unrecognized, yet the patients may propagate the disease. In the septicemic form the glandular swellings may be very slight yet the fever, delirium and prostration indicate severe poisoning, and death ensues in a few hours; or the septicemia may be subacute with tendency to recovery. The pneumonic form is the most insidious in its onset, the most difficult of diagnosis, and the most fatal. The pulmonary signs are not evident for from one to four days after the onset of the disease; then there is pain in the side, difficult respiration, dullness, crepitant and subcrepitant râles, and a persistent cough, with tenacious dark-colored or bloody, or prune-juice expectoration. The consolidation is mostly lobular. In all types there is a tendency to hemorrhage into the spleen, kidneys, spinal cord, and subdural and arachnoid spaces. To sum up, plague is an acute febrile disease of an intensely fatal nature, characterized by inflammation of the lymphatic glands, marked cerebral and vascular disturbances, and by the presence of a specific bacillus. The only curative is the antipest serum of Yersin and Roux, 30 to 50 c.c. of which should be injected at the earliest possible moment. This may also be used as a prophylactic in dose of 10 c.c. repeated every ten days. Among the sequelæ of the plague are boils, carbuncles, chronic suppuration of glands, eruptive skin diseases, and various paralyses.

Tumors of Vermiform Appendix.—In calling attention to the occasional appendix tumors, A. O. J. Kelly (*Proceedings Path. Soc.* of Philadelphia, March, 1900), reports two cases of fibromyoma, three of carcinoma and one of endothelioma. One of the former accompanied fibromyoma of the uterus and gave but mild symptoms. The endothelioma was accompanied by four separate attacks of pain, vomiting, etc.,

leading to the diagnosis of recurrent appendicitis. The appendix was easily outlined by palpation. One of the carcinoma cases gave typical symptoms of acute appendicitis, and pus was found at operation, but microscopical examination showed the malignant growth. Another of the carcinomata caused frequent attacks of abdominal pain, which were always relieved by free purgation.

Gonorrheal Arthritis.—Summing up forty-eight cases, James Stewart (*Montreal Med. Jour.*, March, 1900), finds that all the patients were young adults, six were females, three only gave previous history of inflammatory rheumatism, fifteen had had gonorrhea arthritis before, and in twenty-six it was the first attack of gonorrhea. The arthritis appeared at any time from the third week of the discharge until long after the urethritis had subsided. In most, the urethritis was still active, in some it had become chronic, in four the genito-urinary system was normal. Some cases began with sudden pain and inflammation usually occurring at night; in many the onset was gradual with involvement of one joint and slow extension to others. Most were polyarthritic, some became chronic, many were left with impaired joints or even complete ankylosis. In seven cases the heels and soles alone were affected. Three cases were septicemic with fever and grave constitutional disturbance. The knee was most frequently attacked. Next the heel and plantar fascia, then in order, ankles, feet, elbows, shoulders, wrists, hands, vertebræ, temporomaxillary, sternoclavicular, and thyro-arytenoid. The commonest complication was endocarditis, next iritis. For treatment, salicylates, salol, potassium iodide and alkaline mixtures, and the local application of iodine were valueless. The best results were obtained from rest in bed, low diet, the exposure of the joint to dry heated air at 300° F. for half an hour by the Tallerman-Sheffield apparatus, and hot fomentations, or blisters, with fixation by splints, and, in the chronic cases, massage.

Mothers and Alcohol. — Maurice Nicloux (*L'Obstétrique*, March 15, 1900) reports an extensive series of experiments with the following conclusions: Ingested alcohol passes from the mother to the fetus and into her milk, the proportion in the blood of the fetus, and in the milk being about the same as in the blood of the mother. Therefore the nervous conditions, drunkenness, anesthesia, etc., of the drinking mother must indicate a marked toxicity in the infant, and the whole baneful influence of alcohol upon the tissues is exerted during their process of formation, with especial injury to the nervous supply.

Treatment of Fibroids.—W. Duncan (*Lancet*, April 21, 1900) says fibroids often cause deterioration in general health when they do not produce hemorrhage. Diseases of the heart and arteries are often associated with them. Abortion is liable to occur and the prognosis is grave. Parturition is often dangerous. Operation should be performed only in cases where the symptoms demand it, as in menorrhagia; metrorrhagia; various marked pressure symptoms; increase in size of the tumor, especially after the menopause. Drugs and electricity are merely palliative. Of the various surgical measures, curettage with the removal of polypi and submucous fibroids often gives very great relief. Removal of the appendages frequently fails to stop the growth and the hemorrhages, and the mortality is not insignificant. Morcellement through the vagina and dilated cervix is unsurgical and dangerous except in case of small or polypoid submucous fibroids. Enucleation of large tumors has a far higher mortality than hysterectomy and no compensating advantages. Saving the uterus under these circumstances is a source of danger, for it is unduly thin and in a state of degeneration unsuitable for gestation. These statements apply with equal force to subperitoneal myomectomy. When operative treatment is demanded, abdominal intraperitoneal hysterectomy is by far the best, since its mortality is slight (1 to 2 per cent.) and it gives the best opportunity of examining and dealing with the ovaries and tubes. It is also desirable to leave a small piece of cervix so as to avoid opening the vaginal canal. The ovary and tube of one side at least should be left in if possible, for convalescence is easier, the artificial menopause is not produced, and the sexual feeling remains. The causes of death after hysterectomy are heart failure and intestinal paralysis. For the heart strychnine and brandy should be used for a few days before and after operation. As to intestinal paralysis, prevention is the best treatment. A rectal tube is passed high up every four hours, and if flatus is not passing in twenty-four hours, an ounce of turpentine in a pint of hot water is injected high into the bowel, repeated at intervals of four hours if necessary. Saline aperients are useless. If well-marked tympanites once appears death is almost certain.

Lung Disease Caused by Inhalation of Dust.—On. Bäumler (*Münch. med. Woch.*, April 17, 1900) points out the great resemblance between certain forms of pneumonokoniosis and tuberculosis. The patients are generally advanced in life, poorly nourished, and suffer from cough and muco-purulent expectoration with slight fever. On examination consolidation of one or both apices will be found. The absence of tubercle bacilli in the sputum and the great improvement which follows mere rest and proper hygiene would, however, militate against consumption. Should the morbid process continue, emphysema, putrid bronchitis, bronchiectasis and finally tuberculosis may result. As a valuable physical sign in the diagnosis of pneumonokoniosis, with or without complicating tuberculosis, the author mentions the retraction of the upper anterior lung margin on one or both sides which can readily be demonstrated by percussion over

the sternum and which is sometimes so marked as to lay bare the entire anterior mediastinum.

Diabetic Laryngitis.—Patients whose urine contains an appreciable amount of sugar but whose general health has not yet suffered will often consult the physician for a peculiar dryness of the throat and insufficiency of the voice after use. On examination the posterior pharyngeal wall is found to be dry, smooth, glistening and copper-colored and the vocal cords have a peculiar shiny, glazed appearance. O. Leichtenstern (*Münch. med. Woch.*, April 17, 1900) considers these signs as diagnostic of early diabetes. With proper dieting, the parts will return to the normal, showing that there merely is a hypersecretion without pathological change, although the latter may develop in the form of a sclerosis when the diabetes persists.

Cardiac Hypertrophy in Renal Disease.—A. Bier (*Münch. med. Woch.*, April 17, 1900) looks upon the enlargement of the heart in Bright's disease as a useful, compensatory process. It is well known that the cells of the convoluted tubules remove excrementitious matter from the blood. Since a great number of these cells are destroyed by the connective tissue proliferation an increased amount of work falls upon the remaining ones which require a large amount of fluid to prevent an accumulation of the toxic products within them. Thus follows polyuria, and this again necessitates cardiac hypertrophy. Although the process so far is salutary, it is obvious that the greater strain to which the arterial system is exposed will eventually lead to endarteritis, while finally there must come a time when either the overworked heart or blood-vessels will no longer bear the pressure and degenerative process will occur.

Extirpation of Gasserian Ganglion.—H. Cushing (*Jour. Am. Med. Assoc.*, April 28, 1900) publishes an operation for removing the Gasserian ganglion which necessitates less manipulation of the brain, causes less hemorrhage, and gets the ganglion out in toto more easily than other methods. A horseshoe incision is made, base 4 cm., on the zygomatic arch, convexity slightly higher than the pinna of the ear. This skin-flap is turned down exposing the temporal fascia well down to its attachments to the malar bone and zygoma. Along the outer surface of the zygomatic arch an incision is made through the periosteum which is raised from the upper portion, leaving the masseteric attachments intact, and the ends of the zygomatic arch are cut through by bone forceps. An incision through the temporal fascia and muscle is then made concentric with the skin edge, and the soft structures retracted well down from the temporal fossa which is then completely exposed. With a gouge a small opening is made through the most prominent part of the great wing of the sphenoid and enlarged by the rongeur to 3 cm. The middle meningeal runs on the dura across the opening, and both may be lifted from the middle fossa as far as the firm attachment to the foramen ovale. Between the firm attachments of the dura to the foramen ovale and rotundum the envelope of the ganglion may be split, and by careful dissection its entire upper surface exposed, care being used not to disturb the ganglion itself since its blood-supply comes mainly from below. Then the ganglion is liberated by blunt dissection from the base of the skull, the second and third branches and, finally, the sensory root and first division are liberated, when the ganglion may be removed entire by cutting the three branches and evulsing the sensory root. This order of procedure gives the least bloody field of operation. By staying close to the sensory root one is less apt to damage the cavernous sinus or the sixth nerve. The brain is then allowed to fall back into place, and the muscle, fascia and skin sutured. The wound heals by primary union without drainage.

Tuberculosis of the Skin: Accidental Inoculation.—The danger of inoculation of the skin with tuberculosis, which laryngologists and other practitioners run, is well illustrated by the following case reported by Jay L. Schamberg (*Jour. Cutaneous and Genito-Urinary Dis.*, May, 1900). The patient was a laryngologist who accidentally cut out a piece of the skin about one-eighth inch in diameter on the knuckle of the left thumb with the nail of the right thumb. The cut extended into the true skin. This cut did not heal over for six or eight weeks. Scabs formed over it, but pus collected under each and it broke open again and again. The tissue, after healing around the edges of the scab, became reddened, hypertrophied, and hypersensitive, extending until it was one-half inch in length and five-eighth of an inch in width. This tumor was ovoidal in shape, of a bluish-red color, soft to the touch, and was elevated about one-quarter of an inch. It was smooth except for several small pin-head depressions. It was not warty in character, nor was there any apparent thickening of the horny layer of the skin. The tumor varied in size from time to time and was somewhat compressible. There was slight pain on pressing the growth. The patient was treating two patients for tuberculosis of the larynx at the time he cut himself. The tumor had lasted seven months when the writer made the diagnosis of tuberculosis of the skin and excised the growth. The wound healed nicely and there has been no recurrence in five months. The microscope demonstrated a tuberculous nodule. No tubercle bacilli were found in the few sections in which search was made for them. Two guinea-pigs were inoculated with fragments of the tumor. One died and the autopsy showed extensive tuberculosis. When the other was killed, there was found a cold abscess, containing creamy pus, at the site of the wound, and a number of tuberculous nodules on the liver. Schamberg says that this growth cannot be classed accurately with any of the existing clinical types of tuberculosis cutis.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

EPIDEMIC CEREBROSPINAL MENINGITIS.

EVERY year, especially in the spring, some cases of epidemic cerebrospinal meningitis occur in various parts of the country. Last year a series of contributions from the South and Middle West showed that the disease was not omitting its annual visitation. This year reports show that the disease is not quiescent.

For a time it seemed that the discovery of the meningococcus intracellularis by Weichselbaum solved definitely the problem of the etiology of the disease. Further investigation has shown, however, that the solution is not as simple as at first anticipated. Many of the cases of sporadic cerebrospinal meningitis are due to meningeal infection with the pneumococcus; epidemics of pneumococcus meningitis have also occurred. This infection is often secondary to pneumonia, but is also not infrequently primary. The occurrence of pneumonia during the course of a cerebrospinal fever does not absolutely stamp the affection as due to the pneumococcus. Pulmonary affections resembling very closely croupous pneumonia have been demonstrated to be due to the meningococcus intracellularis.

The mortality of genuine cerebrospinal fever—the spotted fever of the older authors—is, as is well known, very high, more than 50 per cent. of the cases terminating fatally. The prognosis of pneumococcus meningitis is absolutely unfavorable. Not a single case of recovery from the affection is considered ever to have taken place.

Besides these two microörganisms there are others that give rise to cerebrospinal meningitis. Netter is of the opinion from observations in Paris that most of the cases of presumed epidemic cerebrospinal meningitis, in that city, are not due to the Weichselbaum-Jaeger micrococcus, but to one that has certain differential characteristics. It is probable that these forms of the disease can be differentiated clinically as well as bacteriologically and an interesting problem in diagnosis be thus elucidated.

The use of lumbar puncture in this disease, in thousands of cases, shows how absolutely innocuous is this procedure. When the microscopic investigation of the cerebrospinal fluid is positive it constitutes the only absolutely pathognomonic sign of the form of meningitis present. An important aid in diagnosis that has been taken advantage of in very recent years is the microscopic and cultural investigation of the secretion from eyes, ears, and nose. In all of these the characteristic meningococcus has been found. This gives the clue to the mode of distribution of the disease, which, up to the present time, has been a mystery. The necessity for the most careful antiseptic precautions in the disposal of these secretions is now manifest. While the disease has never been virulently contagious, a certain number of cases in every epidemic have occurred among those in immediate contact with patients.

The only therapeutic hint of any promise that is to be found in the recent literature, for, almost needless to say, lumbar puncture has proved of no service therapeutically, is the use of the Credé ointment. A number of cases in the hands of various careful observers have apparently been benefited by this remedy. The affection is, however, so uncertain in its mortality that only encouragement, not assurance, is afforded by the reports.

THE TENEMENT-HOUSE COMMISSION AND ITS WORK.

IT is gratifying to know that the Tenement-House Commission appointed by Governor Roosevelt April 16th, in accordance with the law enacted by the State Legislature during the past winter, has already organized and begun its work.

The progress of its investigations will be followed with constantly increasing interest. The various factors in the case multiply rapidly as the work progresses and lend an ever-increasing fascination.

By the terms of the bill the Commission is directed to make a careful examination into the condition, construction, healthfulness, safety, and rentals of tenement-houses, and the effect of tenement-house life on the health, savings and morals of those who live in them. The attendance of witnesses is compulsory and fifteen thousand dollars has been appropriated for the expenses of the Commission, although the members serve without compensation. There is thus brought under the province of this Commission a study of the widest possible range of sociologic problems relating to the morals, the health and the general well-being of the largest part of New York City's population. These problems are of the first interest to the medical profession and we purpose to study them in their various phases, obtain if possible a more intimate knowledge of the tenement-house question and emphasize to the Commission the pressing need of reform from the standpoint of sanitation.

That the profession may have assurance of the comprehensive scope of this Commission in its make-up and of the earnest the Commission gives of valuable and far-reaching conclusions, it is important to know who are the men that have been selected to serve upon it. And we find that the Commission is composed of physicians, of practical architects and builders, of lawyers who have made a special study of the subject and men who have filled public administrative positions. Then there are representatives of the wage-earners, the tenants and the tenement-house proprietors. So admirably have the members of this Commission been selected that to fully appreciate the excellence of the work that may be expected of them the list is herewith appended:

Raymond F. Almirall of Brooklyn; architect, of the firm of Ingle & Almirall, who studied his profession at Cornell University and the Ecole des Beaux Arts, in Paris.

Hugh Bonner of Manhattan; ex-Chief of the Fire Department of New York City.

Paul D. Cravath of Manhattan; lawyer, of the firm of Seward & Guthrie.

Robert W. De Forest of Manhattan; lawyer and President of the New York Charity Organization Society.

William A. Douglas of Buffalo; lawyer and trustee of the Charity Organization Society of that city.

Otto M. Eidlitz of Manhattan; builder, of the firm of Mark Eidlitz & Son.

F. Norton Goddard of Manhattan; merchant and Aide-de-Camp on the Governor's staff.

Dr. Elgin R. L. Gould of Manhattan; President of the Suburban Homes Company and ex-statistical expert of the United States Department of Labor and an owner of tenement-houses.

William Lansing of Buffalo; architect.

William J. O'Brien of Manhattan; representative of labor organizations and candidate for Sheriff of New York County at the last election.

James B. Reynolds of Manhattan; head worker of the New York University Settlement.

I. N. Phelps Stokes of Manhattan; architect, of the firm of McKim, Mead & White.

Myles Tierney of Manhattan; a retired builder and manager of the New York Catholic Protectory.

Alfred T. White, of Brooklyn; President of the Brooklyn Bureau of Charities, ex-Superintendent of Public Works, and an owner of tenement-houses.

Dr. George B. Fowler of New York; physician and Health Commissioner under the administration of Mayor Strong.

ECHOES AND NEWS.

NEW YORK.

Pauper Labor Abolished.—Commissioner Keller, of the Department of Charities, has extended his crusade against pauper labor in the department hospitals by discharging one-half such hangers-on in Bellevue Hospital.

Vaccination Stations.—The Board of Health has sent out announcements that arrangements for vaccinating children have been completed. One station is located at 68 and 78 Elm Street, where children can be vaccinated daily, except Sunday, between nine and four o'clock. The headquarters of the Department of Health, Sixth Avenue and Fifty-fifth Street, has also been designated as a vaccination station. Children will be received on the same days and between the same hours.

Colored Nurses.—A training school for nurses was established in connection with the Colored Home and Hospital in New York in 1898. It continues in successful operation and the managers are now able to supply colored nurses, who have been well trained in surgical, obstetrical and medical nursing. These nurses are specially adapted to care for people of their own race. There should be a large demand for them, especially in the Southern States.

Licensing Midwives.—The case reported during the past week of a death from septic peritonitis following abortion, criminally performed by Helen Kersten, a professional midwife, again calls attention to the necessity of proper supervision of midwives. The bill now waiting the Governor's signature, however, does not place the supervision in the hands of the proper authorities, and the members of the profession should make their opposition felt by addressing emphatic letters to the Governor.

Warning to Doctors.—A man of somewhat advanced years, introducing himself as Dr. Campbell and displaying credentials from McGill University at Montreal, is going the rounds of doctors' offices asking for alms. Dr. Joseph D.

Bryant and others have been victimized and warn their professional brethren against the mendicant practitioner. A letter from the Registrar of McGill University elicits the information that they know no such man as Dr. Campbell.

Death of Dr. Gray.—Dr. Landon Carter Gray died at his home in New York Tuesday morning, May 8th. Dr. Gray had been suffering for several years from atheromatous arteries and chronic Bright's disease, complicated by heart-lesion. The disease assumed a more acute form about two months ago, confining the Doctor to his bed. He made no mention of his illness, however, and his interest and active work as Chairman of the Committee of Arrangements of the Triennial Medical Congress has been so energetic, that his failure to appear at the opening of the Congress to set the wheels in motion, and the announcement that it was due to illness, came with no little surprise, even to many of his intimate friends. His death occasions sincerest regret to his host of professional friends.

PHILADELPHIA.

Army Nurses.—The Memorial Association of Army Nurses of the Civil War is planning the erection of a monument to deceased members. An entertainment for the purpose of raising funds was recently given, none of those who arranged it having served less than three years during the war.

Health Report.—Deaths for the week ending May 5th were 517, a decrease of 101 from those of the previous week, and an increase of 40 over the corresponding week of last year. Contagious diseases: Diphtheria, 86 cases, 20 deaths; scarlet fever, 78 cases, 6 deaths; typhoid fever, 79 cases, 8 deaths. Influenza is waning, only 8 deaths being reported. One new case of smallpox appeared and the health officials are continually on the alert to prevent the spread of the disease.

Contagious Cattle Diseases.—A total sum of $28,000 has been paid to farmers of the State for tuberculous cattle killed during the past year. Unscrupulous dealers have endeavored to buy diseased cattle and ship them to States where inspection laws are not in force. Anthrax was reported in 12 counties of the State and several persons were infected by the diseased animals. One veterinarian lost his life from being inoculated while making a post-mortem examination of an animal.

Death from Starvation Cure.—The latest fad in medicine in the northeastern part of the city has met with a decided reverse in the death of one of its adherents. Reports of wonderful cures of obesity, dropsy, etc., by prolonged fasting have been plentiful during the past winter. A certain Mrs. Meyer fasted thirty-five days as a cure for chronic rheumatism. Tonicum and physiological salts" were given, but the leader of the starvation cult admits that they contain no food. After the cure of the rheumatism was in sight, as the leader says, the woman died of heart-disease. A physician who was summoned believes that death was due to starvation. The husband accepts the theory of heart-failure.

Academy of Surgery.—At the meeting of May 7th, Dr. Spellisy exhibited methods of head extension in Pott's disease and also a brace for lateral curvature. The latter appliance is very light, consisting of a pad, pressure on which is secured by springs. The apparatus is applied to keep the patient from sagging into the original position between intervals of treatment. It is not curative except as it prevents sagging which would tend to make the patient worse. He finds that the only way to keep patients in the proper position is to apply something of this kind to make them uncomfortable when they relax themselves and tend to assume the old position. He intends to add a brace in front in order to secure pressure upon the deformed ribs.

Dr. Wharton reported several cases of fracture of the leg and of the humerus, the head of the humerus being resected in one case of comminuted fracture. He stated that in the great majority of cases of fracture involving a joint in young persons it was better to cut down and expose the part in order to determine treatment. In discussion Dr. Allis stated that since the days of antisepsis the order of things has been reversed and now he almost dreads a simple fracture instead of a compound. When he can cut down upon a fracture he feels that he has command of it. He recommends cutting down upon fractures of the neck of the femur. In one case seen by him there was good union but the patient had no use of the joint and pain persisted. When the patient died autopsy showed a sharp fragment of bone projecting into the tissues. Laying the parts open at the time of fracture would have prevented this. Such treatment will often relieve pain even if a good limb cannot be secured.

Pathological Society.—At the meeting of April 26th the Society was addressed by Prof. Theobald Smith of Harvard University, his subject being "The Relations of Comparative Pathology to Biology and Medicine." The importance of comparative pathology lies in widening the horizon of the pathologist, the exploitation of human diseases leaving many questions unsolved. Comparative pathology is the study of disease in itself, not as to its cure, etc. The biologist uses facts thus obtained and is in turn succeeded by the human pathologist, the latter furnishing data for the clinician. Experiments determining the effects of diseases upon the higher animals should be the work of governments, and they can afford to maintain an expert for every plague. There should be an alliance between the Government and our higher institutions of learning. Pathology as a phase of biology could be taught in colleges which give courses preparatory to medicine. With animals the disease can be studied as it is

continued in the same species and it can be studied at all stages, as the life of the animal can be terminated at any stage desired. The speaker strongly urges the establishment of institutes for the study of animal diseases.

CHICAGO.

Incineration of Garbage.—Within a week or so some of the city officials will make a trip to Toledo to inspect the garbage-crematory system employed in that city. Specifications for the construction of a plant in Chicago authorized by the City Council in its annual budget, for which $100,000 was set aside, are being prepared and the street officials desire to examine systems in other cities before closing any contracts for the establishment of incinerating plants here. It is the intention to secure a plant that will consume all the waste materials without the separation of garbage from ashes. The new plant will be built on the Bridewell grounds, and when placed in operation will dispose of the garbage in the immediate vicinity of the Bridewell and along the river, from which the material can be easily transported.

Public Health Matters.—Of contagious diseases the total number reported was 108 during the week ended April 28th, of which 61 were scarlet fever, 28 diphtheria, 10 measles, 9 smallpox. There were 9 per cent. fewer deaths reported during the week than the week previous, and the death-rate is slowly assuming normal proportions. Pneumonia, bronchitis and other affections, complicated by influenza during the past three or four months, show the greatest decrease, while the deaths reported from uncomplicated influenza fell from 18 during the week which ended April 21st to 9 last week.

Fallacies of Hypnotism.—At a meeting of the Physicians' Club, April 30th, Dr. S. Kuh presented a paper on this subject. In experimenting with any new remedy there are two questions which we are most anxious to have answered: (1) Is the new remedy as safe as, or safer than, other methods employed for the same purposes? (2) Is it more active in giving relief than other remedial agents? The author cites a number of cases in which hypnotism caused very serious, in some instances even fatal accidents and refutes the statement so frequently made that such accidents are due to improper use, ignorance or carelessness. He points out that hypnotism acts only by increasing suggestibility and that there are other methods of achieving this same end, that any exalted emotional condition, such as hope and fear, will do the same. He refers to a series of experiments made with suggestion in the waking state, for which purpose hypodermic injections of aqua destillata were used and which yielded most satisfactory results. His conclusions are that hypnotism is dangerous, that there are other and safer remedies known to us and that we ought to be particularly careful in its use, because the very cases which are most liable to be benefited by hypnotic suggestion—the neurotic patients—are also most easily and most seriously injured by its use.

Therapeutics of Hypnotism.—Harold N. Moyer discussed suggestion without hypnotism as a therapeutic agent. He said that any discussion of hypnotism must state the theories upon which it rests. Suggestion is no new discovery, nor a new force which had been created during the last few years, but it has existed ever since the nervous system has developed beyond that of a mere reflex mechanism. The older psychologists found no place for the experiments and observations of Braid and Mesmer. The metaphysical conception of the mind which denied reason to animals, made no study of diseased minds, and did not recognize the essential continuity of nervous phenomena, could find no place for observations such as these. The later psychology, which does not make these artificial distinctions and which broadens the term mind to include subconscious mental phenomena, offers an excellent explanation of the phenomena of suggestion. The subconscious mental phenomena may be easily reached by suggestion, if hypnosis is produced. Perhaps it is as readily and even more easily reached in many cases where the individual is awake. In the writer's judgment, hypnosis adds very little to the value of suggestion. In those cases in which it is readily produced, suggestion is quite as efficient in the waking state, and he is of the opinion that persons who are readily hypnotized are injured by the induction of hypnotism if it is frequently repeated. The known dangers of hypnosis should place it always in the hands of trained medical men.

Exophthalmic Goiter with Mitral Insufficiency.—At a meeting of the Chicago Medical Society, May 2d, Dr. Edward F. Wells presented several cases. The first was that of a man forty years of age, of negative personal history, who developed exophthalmic goiter eight years ago. The ordinary symptoms and signs are present, except tachycardia. There is cardiac enlargement and an apical systolic murmur with arrhythmia. Blood examination shows: specific gravity, 1063; hemoglobin, 103 per cent.; erythrocytes, 5,125,000; individual corpuscular richness in hemoglobin, 101 per cent.; leucocyts, 19,400—polymorphonuclear cells, 75½ per cent.; mononuclear cells, 20 per cent.; eosinophiles, 2½ per cent. In comment it was said that the mitral regurgitation in connection with, and probably as a consequence of exophthalmic goiter is uncommon. Attention was called to the bearing which an examination of the blood may have upon the diagnosis of organic from anemic cardiac murmurs. The sphygmograms presented were asserted to be indicative of mitral regurgitation.

Pulmonary Tuberculosis; New Diagnostic Sign.—The patient, a male, has been under observation four years, during which time he has had

four attacks of hemoptysis. Only recently have distinctive physical signs and bacilli in the sputum been manifest. Two weeks ago, and for a week, the evening temperature reached 99.8° F., being normal since. Arterial tension is reduced. Each of the thumb-nails shows five shallow transverse depressions. This sign was present upon the thumb- and finger-nails of two other patients shown. The speaker said that his attention was called to this sign several months ago and he has observed it in a very considerable number of cases since. It was offered as one of the minor contributory diagnostic signs and derives its importance as indicating short and more or less regularly recurrent periods of interference of nutrition, due to febrile attacks. The depressions are usually very shallow. They do not denote the presence of tuberculosis but are present in this affection and in the manner described.

Chlorosis; Method of Blood Examination.—The speaker laid particular stress upon the care required in the management of chlorosis and its tendency to relapse. He is of the opinion that some leading recent authors have, probably unwittingly, minimized these features. In the routine examination of the blood in private practice the following procedures were advocated: The lobe of the ear is rubbed with chloroform and pricked with a Beers' cataract knife; the knife is dipped into the benzole-chloroform mixture and the drop of blood is taken up with the back of the blade from which it is dropped into the above mixture by gently striking the back of the knife on the edge of the urinometer jar; two cover-glasses are now spread and a drop of blood on another cover-glass is put upon a slide; the large tube of the Thoma-Zeiss counter is now filled; a hematocrit-tube is next filled and the flow of blood checked (by the patient) by pressure. The hematocrit is now resolved and the volume of red corpuscles and approximate number estimated; next the Thoma-Zeiss cell is filled and placed upon the stage for settling; next benzole and chloroform are alternately added to the stock mixture (specific gravity 1050), with stirring until the drop of blood and mixture are in equilibrium and take specific gravity; utilize a drop of serum from the hematocrit in the same manner; next count the white corpuscles; next examine the slide of fresh blood for size and character of erythrocytes, roleaux formation, etc.; now fix the dried cover-glass smears and stain, with Ehrlich's tri-acid stain and one with eosine and hematoxylin and examine at once or at leisure. These procedures give information as to the specific gravity of the blood and of the serum; the percentage of hemaglobin, using Hammerschlag's table; the volume and appropriate number of erythrocytes, together with their size, character and tinctorial qualities; the individual richness of the cells in hemaglobin and, lastly, the number, staining qualities and differential count of the white corpuscles. The entire amount of time occupied is not too great to be expended by the busy physician, and most of it may be delegated to an assistant. The extent and character of the information to be gained is of real value.

The American Gynecological Society.—At the recent meeting of the Society in Washington, D. C., the following officers were elected for the ensuing year: President, Ely Van de Warker, Syracuse, N. Y.; vice-presidents, Charles Jewett, Brooklyn, and Richard B. Maury, Memphis, Tenn.; treasurer, J. Montgomery Baldy, Philadelphia; secretary, J. Riddle Goffe, New York; members of the council, Matthew D. Mann, Buffalo; William R. Pryor, New York; Seth C. Gordon, Portland; Joseph Taber Johnson, Washington.

GENERAL.

Health of Boer Prisoners.—The English Under-Secretary for War has made the following statement regarding the condition of the Boer prisoners: In all 3899 prisoners have been confined on board ship, of whom 9 have died; there have been altogether 120 cases of measles, 75 of typhoid fever, and about 30 of other ailments.

Osteopathy Not Illegal.—An osteopathist in Oil City, Pa., has been acquitted of the charge of illegally practising medicine. Judge Criswell decided that present laws have no bearing on this process of healing. The decision is regarded as an important one in establishing the legal status of osteopathy.

Plumbers Seek to Lower Death-rate.—The Journeymen Plumbers' Association wishes to secure improved sanitation in Philadelphia and has asked the aid of physicians in this effort. The death-rate from diphtheria is stated to be higher than in any other city in the country. A plea is made for intelligent, educated men as plumbers in order that the above ideas may be carried out.

Hospital Ship "Maine."—The "Maine" sailed from England for South Africa May 1st. The women nurses, formerly assigned to her, have been replaced by men. No charges are made against the women, either of incompetency or of any other nature; the change is due entirely to economic reasons. Women take up more room than men nurses, and are found physically unable to carry patients up and down from the decks, as is most desirable in passing through the tropics. It is evidently the intention to utilize the "Maine" as a transport hospital ship.

Better Ventilation in Theaters.—The City Council of Chicago will soon investigate the complaints that have been lodged with the Health Department by the Actors' Society of New York against the sanitary conditions existing in a number of the cheap theaters in the former city. The requests for investigation come from persons who have been playing in them. Sanitary Inspector Young has received complaints also of the unhealthful condition of the air in theaters, especially where there are continuous performances.

It is a crying shame that theaters are not so constructed that they can receive the sunlight, which is the best preventive of germ-growth.

American Surgical Association.—The following officers were elected for the ensuing year: President, Dr. Roswell P. Park, of Buffalo; vice-presidents, Dr. J. J. Owens, of Chicago, and Dr. C. Parkhill, of Denver; secretary, Dr. H. L. Burrell, of Boston; treasurer, Dr. G. R. Fowler, of New York; recorder, Dr. De Forest Willard, of Philadelphia. The next annual meeting will be held in Baltimore, May 7, 8 and 9, 1901. The following new members were elected: Drs. Bevan, Harris and Ochsener of Chicago, Dr. McDonald of Albany, Dr. Brewer of New York, and Drs. Oliver and Taylor of Philadelphia.

Physicians Going to Paris.—Under the auspices of the Illinois Medical Association, about three hundred doctors and their families from Illinois, Iowa and Missouri, will visit the Paris exposition in a body. It is expected that there will be at least five hundred in the party when they sail from New York on June 30th. The excursion was organized for pleasure, but many of the leading medical institutions and hospitals on the Continent will be visited.

Aseptic Barber-Shops.—The Boston Board of Health has issued regulations providing definite rules for the management of barber-shops. These rules provide that mug, shaving-brush and razor shall be sterilized after each separate use by immersion in boiling water. The use of powder-puffs is prohibited, and sponges likewise.

The Army Canteen.—By order of the French Minister of War, the army canteen, as it exists in the French army, has been greatly curtailed in its functions. The habitual taking of brandy, absinthe, vermouth, and other spirits, under the guise of *apéritifs* (appetizers) is held responsible for much of the morbid irritability and general demoralization of the rank and file of the army. Henceforth only light wine, beer and cider will be dispensed to the French army canteens.

Funds for the Congress.—At a meeting of the American National Committee of the XIIIth International Medical Congress, held at the Cosmos Club, Washington, May 2d, the secretary reported that already about two hundred American physicians had joined the Congress. It was unanimously voted that the President of the American Medico-Psychological Association be added to the Committee; and farther voted that the organizations the presidents of which compose the Committee be requested to contribute to the expenses of said Committee.

American Therapeutic Society.—In pursuance of a call for an American Therapeutic Society issued by the Therapeutic Society of the District of Columbia, a meeting was held in Washington, May 1, 1900. The organization was effected and much enthusiasm displayed. The following were chosen as officers of the new society which expects to become affiliated with the Congress of American Physicians and Surgeons which meets in Washington every three years. The meetings of the American Therapeutic Society will be held annually, the next meeting being in Washington, D. C., May 7, 1901.

The Plague.—No further news of the spread of the plague has been received from Hong Kong, Japan, Mauritius, or Australia. The most serious condition of the last named place consists in the fact that plague-infected rats have been found in the wharves of Melbourne, Brisbane and Auckland (New Zealand). The advance of the epidemic has not been stayed in India, and the sad news has recently been received from Bombay, May 5th, that a serious outbreak of cholera has occurred among the natives at the famine Relief Works; the deaths average 50 per day. Two hundred of the natives have become panic-stricken and fled from the town.

The Railroad as an Engine of Sanitation.—It is announced that the Sultan has consented to the building of a railway and telegraph line straight to Mecca. There is much more in this than a mere opportunity to satisfy globe-trotting curiosity. The *New York Times*, in remarking upon this, says: "A railroad to Mecca means the penetration of modern ideas to a region where they are woefully needed, and where their absence has constituted a standing menace to the rest of the world. For centuries the Holy City has been constantly receiving and distributing fatal infections on a wholesale scale. The civilized nations have hesitated to interfere effectively with the annual pilgrimages, and after the pilgrims started into the interior they were left entirely to their own devices, which of course have never dealt with anything so irreligious as sanitation. A railroad in such a locality must mean some measure of reform."

The Cuban Census.—The census which has recently been taken under the War Department in anticipation of the approaching elections is now available. From it we learn that the total population of Cuba is 1,572,797; among these there are 815,205 males and 757,592 females; there are 447,372 white males, 462,926 white females of native birth; the foreign whites number 115,760 males and 26,452 females; there are 111,892 male negroes and 122,740 female negroes; the mixed races number 125,500 males and 145,305 females; there are 14,694 male and 163 female Chinese. Of the total population of the Island, 1,108,709 persons are set down as single, 246,351 as married, while 131,787 live together by mutual consent. According to citizenship, over 20,000 are Spanish and more than 1,000,000 are native Cubans. It appears that males are in excess in the total population, except in San Diego, although the female whites outnumber the male whites, except in Pinar del Rio. Only 15.7 of the adults are married. Nearly nine-tenths of the inhabitants were born in Cuba. The officials are gratified to find that the native Cubans constitute so large a proportion of the population, that the

whites greatly outnumber the blacks, and that a large proportion of the native population can read and write.

Artificial Fertilization of Eggs.—Prof. Loeb of the University of Chicago, who attracted considerable attention last summer by his experiments in the artificial fertilization of the eggs of sea-urchins and the production of larvæ after an immersion of two hours in a solution of chloride of magnesium and sea water, has conducted a series of additional experiments during the past winter which corroborate the results of the original investigation. In the later experiments the sea water was sterilized, and the most elaborate precautions adopted in cleaning hands, instruments, and specimens before removing the eggs. If a male animal was encountered in dissection, it was removed, and the instruments were not employed again until they had been thoroughly sterilized. The five ovaries of the female were on removal placed in fresh water, and then put into the sea water, one part of the eggs being placed in sterilized sea water as a control experiment, while the remainder were put in the mixture of water and the magnesium chloride solution. The eggs were left in this mixture for an hour, after which they were placed in sterilized sea water, as many as 25 per cent. developing into blastulæ, and swimming about the next day. The other part of the eggs, however, did not even segment, and the most careful search failed to reveal such a change on the part of any. It was found necessary to use the solution in equal parts and leave the eggs for from one to two hours, in order to secure the segmentation. Prof. Loeb considers that the spermatozoa are entirely eliminated in these experiments, and that his results are accomplished entirely by artificial parthenogenesis.

German.

TWENTY-NINTH CONGRESS OF THE GERMAN SOCIETY OF SURGERY—TREATMENT OF INOPERABLE MALIGNANT TUMORS—CARCINOMA OF THE RECTUM—IMPROVEMENT IN THE TECHNIC OF RESECTION AND AMPUTATION OF THE RECTUM—PHYSIOLOGIC CAUSE OF CHILDBIRTH.

The twenty-ninth Congress of the German Surgical Society was held in Berlin April 18th to 21st. The president, v. Bergmann, in his address of welcome, called attention to the development of the treatment of malignant tumors which the century just closed has witnessed. The first day's session was given up to a discussion of malignant growths.

Czerny spoke of the treatment of inoperable tumors. According to the best statistics 75 per cent. of all surgical carcinomata are inoperable, and according to Dührssen a tenth of the patients operated on for cancer of the uterus are cured. This is a sad outlook, and Czerny said that after much thought upon the subject he had come to the conclusion that it is better to allow a patient with certainly or probably inoperable cancer to die in the expectation of getting well, than it is to subject him to an operation which is sure to be followed in a short time by a recurrence and consequent loss of all hope. Confidence in the doctor is of the greatest importance to such a patient. When he loses it, he is apt to seek a quack. In the treatment of carcinoma three things are especially to be avoided, hemorrhage, gangrene and pain. Many times the ligation of an afferent artery may be of service, *e. g.*, in carcinoma of the tongue. Curetting and cauterization by heat may do good service; or scraping and chemical cauterization, preferably by means of gauze wet with a 20-50 per cent. solution of zinc chloride and used to tampon the cavity may be followed by healing. For surgical cancers an eating paste may be employed. The speaker mentioned an instance in which a carcinoma of the rectum, held to be inoperable, had become movable after the application of a chloride of zinc paste, so that it could be extirpated. Numerous cases were cited in which treatment of curetting, excision and the application of gauze wet with a 30 per cent. solution of zinc chloride had succeeded in effecting a cure of cancerous tumors pronounced to be inoperable by good surgeons. Medicine should also be given internally to satisfy the patient if for no other reason. A rational treatment of cancer can scarcely be expected before some definite knowledge of its nature is obtained. The erection of special hospitals for the treatment of cancer patients, as has already been carried out in New York and London, was advocated.

Krönlein said that the German plan of treating cancer of the rectum has found little acceptance outside of Germany for three reasons, *viz.*, the bad final results; the high mortality of the operation, and the bad functional results in so-called cured cases. From the statistics of eleven clinics he collected 881 cases of cancer of the rectum operated on in the past two decades. One-fifth of these patients died from the operation, one-half of the deaths being due to sepsis. Taking three years as a minimum time limit of freedom from recurrence, Iversen found that one-seventh of all patients operated on were cured. There are, however, well-known instances in which recurrence has appeared at a later period than three years after operation. The indications for operation have been too widely extended. When neighboring organs are involved, such as the bladder or ureters, only harm is done by a radical operation. In the eyes of a patient the question of continence of feces is even more important than the mortality. A healthy anus should always be retained in whole or in part, even although only a narrow circle of mucous membrane remains to connect it with the upper bowel. Krönlein has never made a sacral artificial anus, but has always united the cut ends of the bowel and has obtained thereby, in

39 cases, complete continence in 30 per cent., relative continence in 60 per cent., and absolute incontinence in 10 per cent. In conclusion Krönlein said that extirpation is the sovereign method in the operative treatment of cancer of the rectum; that recovery may be expected in four-fifths of the cases; that a radical cure may be expected in one-seventh of the cases; that it is most important to preserve the lowest part of the rectum in the interests of continence; that the results of total resection of the rectum with the anus are inferior; that the choice of the method of operation depends on the particular case, but that plastic methods are growing in favor.

REHN spoke of improvements in the technic of resection and amputation of the rectum. Since it is difficult to improve early diagnosis of this disease, which often gives no symptoms until it is well advanced, it is especially important that the technic of operation should be most perfect. The sacral method gives a good exposure and is relatively easy to follow; but it is dangerous, it leaves a wound which is not easy to treat, while the preservation of the sphincter ani is often of no value. On account of the disposition of the blood and lymph-vessels—the latter of which are placed entirely on the sides of the rectum—the sacral route is not to be advised. The best method is one which permits a high dissection and easy control of the hemorrhage at the same time that it preserves the fascia and muscular structure of the rectum and avoids infection. Carcinomata which have grown beyond the fascial layer are inoperable. In men the perineal method is far superior to the popular sacral one. If there are no adhesions, dissection is carried up as high as possible through the anterior incision. This wound is then tamponed and the dissection completed posteriorly. A considerable portion of healthy gut above the tumor should be resected with the latter, and the upper cut end of the bowel should be brought down and sutured in position. The subsequent treatment is far simpler than by the sacral method, and the discharge of secretions from the wound is better carried out. Rehn once resected in this manner eight inches of bowel and obtained a satisfactory result. In women the operation is still easier of performance. A simple incision through the vagina exposes well the field of operation. Rehn has operated thirteen times with only one fatality, and in this case there was no retention of secretion in the wound. Movable tumors are easily handled from below. If the lymph-glands are affected it is necessary to open the abdomen. Experience with this combined operation is still limited. The perineal method preserves to the greatest possible extent the normal relations of the parts. An artificial anus will rarely be required—only in an extreme case as a temporary measure. A valid objection to the sacral method is the loss of sphincteric action. Gangrene may follow amputation of the gut high up, because of lack of nutrition due to too great tension when the gut is brought down and sutured.

At the Imperio-Royal Society of Physicians in Vienna, April 6th, J. THENEN explained the onset of labor in childbirth in the following manner: The fetal circulation is complete in itself. The placenta receives all of its nourishment from it, and that, too, only after the blood has passed through the embryo. The greater the embyro becomes, the less nutritious is the blood which leaves it. Accordingly, the growth of the placenta ceases after the embryo has reached a certain size (thirty-sixth week of pregnancy), and from that time on the degeneration in its structure begins, evidences of which are visible in every placenta at birth. The placental labules begin to loosen their hold on the uterus. The specific influence which the living impregnated ovum has exercised on the female organism, and especially on the uterus, and by reason of which the uterus and ovum have lived as one organ, disappears, and the uterus resumes its normal functions and forces out the foreign body in its cavity. Thus there is no new irritation introduced. The cause of the birth is not to be looked for in uterine changes, or changes in the membranes, hemorrhages, fever, etc., but in the cessation of the influences which pregnancy exerted upon the uterus and which for a time held in abeyance the normal uterine functions. This theory explains not only the origin of labor but the typical duration of pregnancy.

SOCIETY PROCEEDINGS.

ASSOCIATION OF AMERICAN PHYSICIANS.

Fifteenth Annual Meeting, Held at Washington, D. C., May 1, 2 and 3, 1900.

(Continued from page 721.)

THIRD DAY—MAY 3D.

Adult Filaria Specimens.—Dr. W. T. Councilman of Boston presented specimens of adult filaria from a patient who lived for twelve years in the Barbadoes. Chyluria had not been noticed and anemia was not present. An abscess developed in one of the testicles from which came a yellowish discharge. In the discharge filariæ were found. The testicle was removed and on section coiled masses of worms could be easily picked out. A characteristic group was shown consisting of six individuals, four females and two males. When the testicle was placed in warm salt solution for some time, some of the living worms crawled out to the surface and could be picked off. Careful studies of the parasites were made and sketches of various anatomical features drawn. Very striking features were the head and the relations between the uterus and the digestive tract. The mouth consists of a dimple shaped not unlike a maltese cross. The uterus and the intestine lie in a coil each wrapped around the other.

The blood of a brother of the patient when examined during the day showed nothing abnormal. Examined during the night it showed numerous active filariæ. The brother also lived for some years in Barbadoes, but has absolutely no symptoms nor inconvenience from the presence of the worm and says he has enjoyed excellent health for years.

Rashes and Diphtheria Serum.—Dr. William H. Park of New York said that in fifteen per cent. of the cases in which diphtheria serum is used cutaneous rashes, urticaria, erythema and the like and occasionally some joint symptoms develop. These are not severe and never seem to leave any serious sequelæ. It would be extremely helpful, however, to the cause of antitoxic treatment if these rashes could be done away with. There is, of course, a large personal element in the patient's reaction which causes the development of the cutaneous symptoms. This personal idiosyncrasy is extremely capricious and occurs in very differently constituted people. Nothing that the manufacturers of antitoxin have so far done has succeeded in modifying the tendency to the production of rashes. Filtration, as anyone who has experience in the matter knows, has absolutely no effect. A fine filter requires a great deal of care in its use and yet seems not to do the least good in removing the source of the cutaneous symptoms. Spronk suggested that the serum should be heated to 58°C for twenty minutes. This method of treating serum was tried in New York, but seems to produce no effect. Twenty cases were treated with serum that had been heated and twenty cases with unheated serum from the same animal. No difference in the number of rashes that occurred could be noticed.

Improvement of Serum.—The only successful method for the improvement of the quality of the serum so far found is to select the animals and the bleedings in order to eliminate undesirable samples of serum. It has often been noted that the serum of certain horses is much more liable to produce rashes than is that of others. After trial such horses are now no longer used. It has also been noted that the blood taken at certain times contains more irritant properties than at others. There is nothing in the appearance of the serum, or any quality that can be determined by chemical tests which will show that the serum is in a particular case likely to be irritant. This can only be determined by actual trial. Specimens of each bleeding are now given to inspectors who use the serum on cases reported by the Department of Charities to the Board of Health for treatment. The number of rashes found under the use of any particular serum is noted and where the percentage is high that serum is not put on the market for general use. Under this system of inspection a serum has been obtained with which sixty-five injections were given at a hospital and but two rashes resulted. As the percentage of cutaneous symptoms from some sera runs as high as thirty per cent., it can be seen that this is a very decided improvement.

Globulin in Antitoxin.—It has long been known that in the globulin that can be precipitated from antitoxic serum most of the antitoxic properties of the serum are contained. Either the globulin itself holds the antitoxin or it is mechanically precipitated when the globulin is thrown down. Observations in New York would seem to show that the precipitation of the antitoxin at the same time with the globulin is not merely a mechanical process. The globulin in serum and its antitoxic properties bear a certain relation to each other. Recently in an untreated horse in the laboratory of the New York Board of Health the serum was found to contain three units of antitoxin, which is a remarkably high amount. The serum contained also three and two-tenths per cent. of globulin, which is considerably more than normal. At the end of several months of treatment and at a time when the blood contained twelve hundred units of antitoxin there had been an enormous increase in the globulin up to eight per cent. Later when the antitoxic properties were somewhat exhausted, the units of antitoxin value and the amount of globulin both dropped. Serum globulin has been obtained reasonably pure from diphtheria serum and then has been dissolved in water in the hope of thus eliminating the objectionable properties of antitoxin. It has been used in twenty-four cases in twenty-three of which recovery took place. This globulin antitoxin has, however, proved rather irritating. Slight abscesses formed at the point of inoculation in several cases. Despite the removal of the other albuminous substances contained in the serum, cutaneous symptoms sometimes occurred. The problem, then, of the production of a non-irritating serum is not yet solved, although a step in the right direction seems to have been taken.

Dr. McPhedran of Toronto said that the question of the occurrence of cutaneous rashes was largely a matter of personal idiosyncrasy. Recently in a family he had occasion to give immunizing injections of serum to a mother and child and the child's nurse. Only very small amounts of serum were employed. Neither the mother nor child developed any symptoms. In the nurse there occurred an urticaria with some fever and joint symptoms and general indisposition which lasted for ten days.

Dr. Meltzer of New York suggested that perhaps one serum which produced symptoms would protect against the development of any further symptoms from the same sort of serum.

Dr. William H. Park said that he has seen repeated rashes occur in certain cases where repetitions of the same serum were given. It is doubtful whether the repetition of the injection brought out the rashes after the first one, or whether they would have occurred off and on for some time as they do sometimes after a single injection of serum. This experience, however, would seem to hint that the serum is not protective. Dr. Park has seen in Boston the employ-

ment of large injections of antitoxin where the antitoxic strength was not high and where consequently much larger doses of serum than usual had to be employed. The cutaneous symptoms were neither more frequent nor more severe although the joint symptoms seemed to give more trouble.

Varieties of the Diphtheria Bacillus.—Dr. F. F. Westbrook of Minneapolis detailed some work on the varieties of the diphtheria bacillus which has been done by Drs. Wilson and McDaniel and himself for the Minnesota Board of Health. He said that the great variability of the diphtheria bacillus makes it important for us to have some definite classification. The old division into typical and atypical diphtheria bacilli is no longer of any use. Three great families may be admitted. In the first the material of the bacilli stains in granules. Usually these granules are at the poles while the staining of the intermediate body of the bacillus varies in intensity. Certain branched forms of the diphtheria bacilli seem to come under this group. The second group of bacilli consists of the barred forms. In these it looks as if cross-sections of the bacilli were removed. Sometimes the intermediate portions are distinctly stained, but are of a much lighter blue than the other parts. The size of the light areas of the bacilli are very different. This gives rise to a variety of types. The third group consists of the solid color forms, in which the whole bacillus takes the stain rather uniformly. Under this group come the diplobacilli although these were formerly classed as pseudobacilli. A specimen from any throat may contain a number of these groups, although often some one group either predominates or exists exclusively. The progress from one group to another may be noticed in the throats of patients, but this progress is not typical of the course of the disease, and tells nothing as to the prognosis of the case.

In the discussion Dr. Abbott said that the normal morphology of the diphtheria bacillus is not known. This makes it very difficult to interpret the variety of forms which are found. If we alter the environment on which the bacillus grows we get very different types. Simple acidification of the medium makes a great change in the appearance of the bacilli. The morphology of the diphtheria bacillus is much more complicated now than it was eight years ago when Loeffler's blood-serum was used as a culture medium. The coagulation of the medium makes a distinct difference in the appearance of the bacilli. The solid color group would seem to consist of involution forms. A pathological process has gone on in the microbes themselves, making them much more susceptible to the stain.

Diphtheria Bacillus in Healthy Throats.—There is no doubt now that genuine diphtheria bacilli may occur and exist for a good while in healthy throats. These bacilli are virulent, but the patient is not at the moment susceptible to infection. Often in these cases a mild injection of the throat exists, indicating that the superficial layer of tissue is somewhat affected by the presence of the diphtheria bacilli. It is these very mild cases which are important to public health and which create such a difficult problem for health authorities to solve. Undoubtedly these cases serve to spread the disease. They have so few symptoms, however, in some cases none, that it is a hardship to prevent them from going about their business. This prevention, however, is for the public good and should be insisted on.

Dr. Park said that he did not think that the members of the third group, the solid color forms of the diphtheria bacilli ever occur in original cultures. The diplococcus forms are not considered by the New York Board of Health to be true diphtheria. Where bacilli resembling diphtheria bacilli occur in healthy throats, the question always arises, are they virulent? The only way to decide is to inoculate guinea-pigs and wait four days to see whether infection takes place. Where diphtheria bacilli occur in the throat it is extremely difficult to say whether the person shall be allowed to go about freely or not. Sometimes it constitutes a most discomforting problem. There seems to be no doubt that virulent bacilli can exist in healthy throats without producing any effect. Patients are not susceptible to a given moment and their tissues are capable of resistance. The present practice, at present so common, of immunizing children for measles is founded on this fact. Healthy children resist the invasion of the diphtheria bacilli; when weakened by measles, however, they succumb to it. As in institutions the diphtheria bacilli seem to exist in most children's throats, there arises the necessity for immunizing against diphtheria when they are weakened by a disease that affects the throat tissues.

Dr. Meltzer said that the appearance in certain groups of the diphtheria bacilli, especially in the barred forms, resemble those that are caused in bacteria by plasmolysis. This is a phenomenon due to variations of osmotic pressure, the liquids in which the cellular elements are contained being of very different specific gravity to those existing within the cell-wall of the bacteria.

Dr. Westbrook, in closing the discussion, said that the virulence of diphtheria bacilli for guinea-pigs by no means necessarily implies their virulence for human beings. It is true this is the only way in which to decide as to virulence, but it is fallacious.

Addison's Disease Treated with Suprarenal Extract.—Dr. W. W. Johnston of Washington presented a patient suffering from Addison's disease. The young man, who was twenty years of age, presented himself in the fall of 1807 suffering from extreme weakness and with beginning bronzing of the skin. He was ill for some time and grew worse as the colder weather approached. He was in bed for some months. In the spring-time he improved and enjoyed reasonably good health during the summer. In the fall of 1808 he again became weak, pigmentation in-

creased, and he was troubled with vomiting and diarrhea. He improved somewhat and in October, 1899 he had another aggravation of his malady. Each relapse was worse than the preceding one and made his general condition more serious. Under the rest treatment he improved rapidly and gained twenty pounds in weight. The administration of suprarenal extract seemed to be of benefit. Since then he has continuously gained in strength. His pigmentation has not decreased. His blood has four and one-half million red cells and is otherwise normal. He has some enlargement of the liver, but there is no glycosuria. He has continually a subnormal temperature. The pigmentation occurs in mole-like spots, but there is also a general bronzing of the skin. His extremeties especially are very dark.

Of the forty-three cases of Addison's disease in medical literature that have been treated with suprarenal extract, thirteen have improved. In this case it has not been necessary to increase the doses of suprarenal extract, but he has gone on improving on the original dose. His arterial tension increased very markedly at the beginning of the treatment and his heart acted better. This improvement has continued.

Venous Thrombosis in Cardiac Disease.—Dr. William H. Welch of Baltimore said that he has now seen four cases of this complication, three of them at the autopsy table. In the text-books peripheral venous thrombosis is not treated of as a complication of cardiac disease. His personal experience would seem to point to the fact, however, that a sufficient number of such cases occur to make the affection of importance clinically. Dr. Welch's first case was a negress, seventeen years of age, suffering from aortic and mitral insufficiency. She developed suddenly a swelling of the neck and a painful, hard edema of the left arm. The veins of the arm and neck could be felt as cords. The pulse became intermittent and the patient died. At the autopsy complete pericardial obliteration was found, while a large thrombus existed in the left innominate, the jugular, the subclavian and the axillary vein. The oldest part of the thrombus was somewhat greyish in color and occupied the bulb of the jugular vein. Cultures were made from various parts of the body and all of them were sterile except those made from the thrombus. Here the streptococcus was found in pure culture. The cause of the thrombosis was evidently this infectious agent.

The second case terminated in recovery. Mitral stenosis existed, but the compensation was not very much disturbed. The left ankle became swollen and tender and then the left side of the neck swelled. A temperature of 100° F. developed and the pulse-rate went up to 124. The swelling of the neck increased and the jugulars stood out as hard, sensitive cords. A week later the left arm became swollen and a condition of hard, tender edema developed. This was evidently due to genuine phlegmasia alba dolens and was not the soft edema of heart-disease. After two months the collateral circulation was restored and the patient recovered. During the course of the case embolism of the popliteal artery took place, but gangrene did not set in and the collateral circulation was also restored here. In the third case edema of both arms developed, but the left arm was harder, larger, whiter, and more tender than the right. The left brachial, axillary and subclavian veins were thrombosed. In the fourth case the left femoral vein was thrombosed. This case was evidently, however, of a very different category to those in which thrombosis occurs in the arm and neck. In the literature there are twenty-seven cases of peripheral thrombosis in heart-disease. Twenty-three involve the head and neck and the arm, while only four occurred in the lower extremity. It is possible, of course, that thrombosis in the lower extremity might be overlooked because of edema from insufficient elimination of urine due to the heart-disease. It would seem, however, that other reasons besides this are at work. Seventeen of the twenty-seven patients were females. The affection is almost limited to mitral lesions, especially to stenosis of the mitral orifice, and this form of endocarditis is very common in women. The youngest patient was nine years of age and more than one-half the cases were under thirty years of age, so that it is distinctly an affection of early life. In twenty cases mitral disease existed; in one relative insufficiency of the mitral existed in connection with aortic disease. These cases are sometimes spoken of as rheumatic phlebitis, but there seems no reason for this name since no typical symptoms of rheumatism occur. There is a great predominance of the complication on the left side. In only two cases did it occur on the right side alone. It was bilateral more commonly. By far the majority of the cases were exclusively on the left side.

The first symptom is swelling or pain, at times one, at times the other. Very often the complication is missed entirely because the constitutional symptoms are masked by the bad condition of the heart and the symptoms it occasions. There is nearly always a slight rise of temperature. In a case that was studied very carefully by Dr. Helen Baldwin the buccal temperature was six degrees lower than the rectal temperature, which was slightly above normal. As a rule, death takes place because of the heart-disease rather than from the presence of the thrombus. The reason for the greater frequency of thrombus on the left side is that the left innominate is longer, is more oblique, and there is more obstruction by valves on this side of the venous circulation. Recklinghausen has called attention to the fact that a whirling motion in the blood favors thrombosis. A vertical movement occurs especially in the bulb of the internal jugular. Imperfect valves often exist in this vein and these add to the cross current. Besides there is often systolic reflex in these cases of mitral stenosis and insufficiency. Something more than these mechanical factors, however, is needed in order to precipi-

tate thrombosis. This added factor is an infectious agent.

In the discussion Dr. Kinnicutt of New York said that edema of the left arm and swelling of the neck and side of face with cord-like induration of the veins in these regions were the cardinal symptoms in a case which he saw some months ago. The patient was restored to health although the collateral circulation was not completely developed. Just before leaving New York he was again called to see the patient and found that thrombosis had occurred in the veins of the left lower extremity. Serious constitutional symptoms then developed and threatened a fatal termination.

Dr. Cary of Buffalo said that another important factor that causes the thrombosis to occur on the left side rather than on the right is the fact that the dilated heart presses upon the veins upon this side more than on the right and so adds another mechanical factor to those mentioned by Dr. Welch.

In closing the discussion Dr. Welch read from his paper a passage omitted in the previous reading in which he mentioned the fact that in cases of mitral stenosis the dilated left auricle presses upon the veins on this side and so adds to the liability to thrombosis. It also presses upon the artery, causing the left radial pulse to be less than that on the right, one form of the pulsus differens of the clinicians.

The New Tissue in Cirrhosis.—Dr. Simon Flexner of Philadelphia demonstrated specimens of cirrhosis of the liver treated by Weigert's stain for elastica and by the digestion method in order to determine what the new connective tissue in a cirrhotic liver is composed of. A student in Ziegler's laboratory recently announced that the new connective tissue in cirrhosis is mainly composed of elastica. This seems true if staining methods alone are depended on. By exposing the tissue to digestion by pancreatin all the elastica is removed. A white fibrous tissue with a reticulum is, however, left. The opposite method was also tried, *viz.*, that of removing the white fibrous tissue by caustic potash. A certain amount of success was attained. The digestion process showed that the new tissue in hypertrophic and atrophic cirrhosis are very differently composed. The cirrhoses have been unfortunately named. In biliary cirrhosis, for instance, the connective tissue forms around the blood-vessels while from the name it would be expected to form around the biliary ducts.

Cystoma of the Pancreas.—Dr. Fitz of Boston reported a case of cystoma of the pancreas which had been diagnosed and removed by surgical operation. There are only seven cases in the literature in which the diagnosis has been made. This tumor differs somewhat from a retention cyst of the pancreas although it produces the same clinical symptoms. The structure of the tumor seems to suggest that it originates from a proliferation of the acini of the glands and a dilatation of the smaller ducts.

Dr. J. H. Musser's paper on "Subpectoral Abscess" was read by title, as was also Dr. D. D. Stewart's paper on "Stone in the Kidney and Conditions Simulating It."

Aneurismal Rupture into Superior Vena Cava.—Dr. Alfred Stengel of Philadelphia reported a case of aneurism of the aorta which ruptured into the superior vena cava, the condition being recognized during life. The patient was a workman, thirty years of age, who felt something give way in his chest, after which an intense sense of oppression developed. Great swelling of the neck and upper part of the body down as far as the waist line ensued. The lower part of the body was perfectly normal. Great cyanosis also developed. Death took place only after twenty-four days. It is surprising how long the duration of such cases is. One patient was alive seven months after the condition developed. In another case recovery seems to have taken place. The great lividity would tempt an attending medical man to do venesection. It is probable, however, that venesection would do more harm than good. It prevents the equalization of pressure by the venous blood which would cause clotting in the aneurism itself and so lead to the only hope of relief from the condition.

Cardiac Dilatation.—Dr. Beverley Robinson of New York reported some minor forms of cardiac dilatation, especially those which occur in chlorotic girls just past puberty. For these cardiac stimulants are necessary, but general roborant treatment is more needed and produces more lasting effects. Very often there is excessive menstruation, which should be controlled by ergot or hot douches. Not infrequently in these cases there is some albumin in the urine and slight febrile temperature develops. In one case a patient was told that nephritis existed and she was advised to seek another and more equable climate. The fact of the matter is that the heart in these cases is not able to keep the blood-tension in the kidney high enough to cause the excretion of normal urine. The indication is for treatment of the heart and not of the kidneys.

Graves' Disease Without Exophthalmic Goiter.—Dr. W. H. Thomson of New York reported a number of cases of Graves' disease in which tremor, some constipation or diarrhea, and tachycardia existed, yet without goiter or prominent eyeballs. The speaker discussed the symptoms of sixty-six cases seen in private and consultant practice. Of these thirty-four had both the enlarged thyroid and exophthalmos. Thirty-two of them had neither the exophthalmos nor the goiter. The symptoms in these two classes of cases are so similar that Dr. Thomson considers them to be practically a demonstration that the thyroid gland and its affections are not of the essence of Graves' disease at all. He suggested that the pathology of the disease will have to be looked for elsewhere.

The paper of Dr. D. D. Stewart of Philadelphia, entitled "A Case of Acute Graves' Disease without Exophthalmos or Goiter," was not read.

In the discussion Dr. McPhedran of Toronto said that he has seen cases of Graves' disease in which there was no projection of the eyes beyond the normal, but in which, despite the presence of considerable emaciation, the eyes had lost none of their normal prominence, that is, while there was not absolute, there was relative, projection of the eyeballs.

Dr. Thomson said that an enlargement of the palpebral fissure without striking projection of the eyes was not an unusual symptom in Graves' disease, and it sometimes is a substitute for the exophthalmos.

Perichondritis of the Larynx in Typhoid.—Dr. M. H. Fussell of Philadelphia said that this complication is very rare, occurring only in a little more than one per cent. of the cases. He has seen two cases, one of which proved fatal. The disease began on the fifth day after the typhoid temperature had become normal. The man ate a piece of apple and on swallowing it had a sensation of suffocation. Symptoms of stenosis developed shortly afterward and swelling and tenderness of the larynx externally were noted. The breathing became so labored that Dr. Fussell advised tracheotomy, but stupid relatives would not be persuaded of its advisability.

The second case was a typhoid convalescent in the thirteenth day after the temperature had become normal, when a chill developed. This seemed to be due to an abscess in the arm, because as soon as the abscess was emptied the fever disappeared. At this time it was noted that the breathing was stridulous when the patient was excited and was somewhat noisy during sleep. Symptoms of laryngeal stenosis developed, tracheotomy was done and a tube was inserted. The abscess opened two days after the insertion of the tube and it was evident that the pus collection never would have emptied itself with safety to the patient if the tube had not been inserted. Afterward the necrotic arytenoid cartilages were coughed up. Complete ankylosis of the crico-arytenoid joints developed and also of the vocal cords. The tube remained in place for five months and then was removed for a while, but had to be reinserted. After having practised occlusion of the tube for some hours at a time, it was removed again. It was always discomforting to the patient to have it out during the night. But at the end of six months this also was accomplished. There are only twelve cases in the literature in which it has been possible to dispense with the tube. Cases of perichondritis occur oftener than is suspected, but as the patients are very weak, the symptoms are missed and sudden stenosis occurs with fatal termination.

The Appendix in Typhoid.—Dr. Hobart Amory Hare said that it not infrequently happens that during typhoid appendicitis develops as a complication. As typhoid with appendicular symptoms is not uncommon, there will be some hesitation in operating for the appendicitis because the existence of typhoid makes the prognosis after operation so much worse. The differential symptom is the presence of leucocytosis in appendicitis. This may be slight, but it is sure to occur if there is a purulent focus. Notwithstanding the fact that typhoid makes convalescence from an operation for appendicitis less assured, operation should not be neglected where it seems necessary. If the abdomen is scaphoid and the muscles are board-like and rigid, if there is tenderness in the right iliac fossa and pain over the appendix, then an operation should be performed even although typhoid be present. The blood examination will make the decision less difficult. Leucocytosis as is well known does not occur in simple typhoid.

Appendical Symptoms in Typhoid.—A number of cases of typhoid occur in which there is pain and tenderness over the region of the appendix. In one case recently under Dr. Hare's care, McBurney's point was especially tender. There was the board-like tension of the abdominal walls. A prominent surgeon suggested operation. This was about to be performed when the appearance of the tongue, which was very characteristically typhoidal, prompted delay. Salines were given and an ice-bag applied. The symptoms remitted some the next day and at the end of a week all the appendical manifestations were gone and typhoid frankly declared itself.

Observations on Appendicitis.—Dr. Ira Van Gieson of New York said that the predisposing factors of appendicitis are important. The appendix is prepared for acute attacks by a chronic obliterative process due to a new growth of connective tissue. This new growth of connective tissue is really due to disturbance of the circulation of the appendix. During the development of the appendix the fact that the vessels are pressed upon by the ileocolic falx and also the fact that the meso-appendix is so short as to make the vessels describe a curved course render them liable to obliterative endarteritis. The exciting cause of appendicitis is always bacteria. The principal bacterium concerned is the bacillus coli communis, although the streptococcus pyogenes and the pneumococcus are also of etiological significance. The bacteria are, however, only able to accomplish their invasion of appendical tissues when the appendix is lowered in resistive vitality by affections of its blood-vessels which disturb its circulation. In more than one-half the cases the appendix has undergone more or less obliteration before the middle of life has come. Appendicitis is an important evolutional factor by which the survival of the fittest is accomplished. As such it performs a great purpose in the scheme of evolution.

The paper of Dr. Andrew H. Smith of New York, entitled "Would it not be a Gain to Both Pathology and Practice if a Direct Interaction Between the Morbific Agent (Noxa) and the Reparative Efforts Were Recognized and the Conception of an Intermediate, So-called Inflammatory Process Abandoned?" was read by title.

Human Temperature in Disease.—Dr. Norman

Bridge of Los Angeles, Cal., said that treatment is less difficult than diagnosis. The cause of fever is still often enough a mystery. It is thought to be due to the toxins which are usually produced by microbes, acting upon the nervous mechanism which regulates heat production and heat dissipation. Besides these septic products there are albuminous products from certain organs that seem to produce the same effect. Inflamed follicles in the tonsils may cause fever and yet resolve without the production of pus. We do not as yet know how much fever the tubercle bacillus is capable of producing. It is probable that most of the fever which occurs during the course of tuberculosis is due to secondary infection, or to the breaking down and absorption of necrotic tissue. The sudden fevers which occur in childhood are usually thought to be due to ptomains from the digestive tract, but this is pure hypothesis as yet unproven. It is not known for certain whether nervous perturbation ever may cause fever of itself without any chemical influences within the body. It is known, however, that people who are feverish are made worse by emotion, but normal people seem not to be so affected. Exercise certainly does increase fever as also do emotions in tuberculosis, so that both of these are avoided as far as possible in sanitoria. The existence of purely hysterical fever has been doubted, but it probably exists. Formerly the great scapegoat in diagnosis wherever fever existed was malaria. Now it has become grip. There is a great temptation to treat fever, but it should be resisted, unless other symptoms besides the fever develop. If nervous symptoms develop, they can be best treated by baths. Fever may last for months, as occurs so often in tuberculous cases, yet without producing any serious constitutional results. Aconite has been very much used during the last half century to reduce fever. It never does it except by injuring the patient. It may make the patient less nervous by quieting the heart, but more than this it does not accomplish. Certain things for the treatment of fever may be done. Purulent products may be removed, so as to prevent further absorption. Inflammation may be allayed, and catharsis will eliminate from the intestinal tract substances the retention of which might produce fever.

Infantile Paralytic Mummy.—Dr. J. K. Mitchell of Philadelphia described a mummy found by the Flinders Petrie expedition in a village south of Cairo, on the edge of the plain. The date of the mummy is 3700 B. C. It was found enclosed in a coffin made of a sycamore tree, careful estimation of the rings of which showed it to have been at least 300 years old. One of the legs of the mummy is considerably shorter than the other. At first it was suspected that a thigh was broken. There is no evidence of this. A staff was found in the coffin with the mummy. Notwithstanding this there is no evidence of any tilting of the pelvis or any curve in the spine. It seems clear, then, that some prothetic apparatus was used upon the lame leg so as to compensate for its shortness. This was probably a high-soled shoe of some kind. The femur of the lame leg is shorter and smaller in diameter than the femur on the other side. This seems to point to an atrophy of the part. This atrophy was probably due to an anterior poliomyelitis, occurring at a very early age, or perhaps even in intra-uterine life. This is the earliest case of anterior poliomyelitis on record. The earliest case of infantile paralysis known before this was that of Jonathan's son Mephibosbeth who, Professor Osler thinks, was affected by the disease.

A Modified Sphygmograph.—This was presented by Dr. Robert T. Edes of Jamaica Plains. Dr. Edes thinks the idea that the sphygmograph can give any information as to the kind of heart lesion that exists has been given up. It is possible, however, to learn something from it as to the pulse tension. What is needed, then, is an especially accurate mechanism for the magnification and correct reproduction of the arterial tension. This, Dr. Edes thinks, he has accomplished.

The paper of Dr. Morton Prince of Boston on "The Circular Fibers of the Heart (Mitral) Sphincter as a Factor in Functional Disturbances of the Heart with Mitral Insufficiency," was read by title.

AMERICAN PEDIATRIC SOCIETY.

Twelfth Annual Meeting, Held at Washington, D. C., May 1, 2 and 3, 1900.

(Continued from page 726.)

Third Day—May 3d.

A Case of Rachischisis.—Dr. T. M. Rotch of Boston presented a paper on the above topic, and said that it is one of the principle forms of congenital defects of the spine. It is characterized by a deficiency, either complete or partial, of the vertebral arches. The cord is rudimentary and is split open so that the endothelial lining of the central canal is exposed. The condition is of interest pathologically rather than clinically. The case in question came under his notice at the Infants' Hospital. A girl, three years old, was admitted to the Hospital on February 14, 1900, in the service of Dr. John Dane. The history of the case was that the delivery had been with forceps, but the infant was viable and it had taken no food since birth. A physical examination showed the head to be of normal size. The anterior fontanelle was widely open. There was a caput succedaneum on both sides. The face was flattened, chin retracted and held in forced position with the occiput on the principal dorsal spine. The skull was apparently well over. The foramen magnum was as large as a silver dollar. The section of the brain passed nearly through the median portion of the brain which was poorly hardened. Neither the cerebellum nor the pons was to be found in the cranial cavity.

Fatal Post-Optic Cerebral Abscess, with Amnesic Aphasia.—Dr. J. Henry Fruitnight of New York, in presenting his paper, stated that this case illustrates the extent and gravity of a pathologic lesion. The patient, Fannie W., twelve years of age, of New York City, came under his care December 10, 1899. In June, 1898, she had suffered severely from an acute otalgia of the left ear. This happened in the country. She consulted a physician who diagnosticated otitis with an abscess. He did a paracentesis of the drum of the left ear, evacuating a large amount of pus. The mother was instructed how to proceed in the treatment, but neglected to continue it. When the speaker first saw the patient her temperature was about 100° F., pulse 98, and she complained of frontal headache. There was some prostration, and she had occasional chilly sensations and nausea. There was a scanty discharge from the left ear. The clinical diagnosis was a deep mastoid caries, possibly cerebral abscess and beginning meningitis. December 17th she was seized with violent convulsions which continued six hours. They were finally controlled by the use of a rectal injection of chloral hydrate, inhalations of chloroform and hypodermic injections of morphine.

Dr. Herman Knapp of New York, who had seen this patient and made a clinical observation, said that this case was remarkable and instructive. Before the operation the location of the abscess, if it was assumed from the symptoms, would be higher up than where it was found. The operation revealed a condition which showed conclusively the presence of an abscess, the site of the disease being the bones of the ear. There was some congestion, but not so much as to indicate the condition.

Dr. Henry D. Chapin of New York called attention to the mastoid trouble in children in which the brain is not affected. It is well to note that where the mastoid disease does not affect the brain but burrows in front, it is best to look in that region. He reported the case of a boy, five years of age, in which there was tenderness back of both ears but no swelling. The temperature fell from 103° to 101.5° F. and remained there for a day or two.

Dr. Fruitnight, in closing the discussion, referred to the absence of low pulse and high temperature.

Measurements of Chicago School Children.—Dr. W. S. Christopher of Chicago presented what was probably the most interesting and instructive paper of the session. It was fully illustrated by charts and by the instruments used in taking the measurements of the school children. The observations represented measurements of ordinary anthropometry measurements and in addition the results or work of the ergograph. The ergographic work was so done as to express in cm. kilograms in place of pounds, the amount of energy exerted by each pupil tested. The test consisted in lifting at each alternate second with the middle finger of the right hand a weight equal to 7 per cent. of the gross weight of the individual and permitting them, at the next second, to return. The test was continued in each case for ninety seconds, during which time this weight was lifted forty-five times, the time being guided by a metronome beating seconds. Before the end of the ninety seconds was reached in each case the child would show signs of fatigue which was exhibited in an ergogram. On comparing the ergogram work of children of different ages, it was found that the work done by girls was less than that done by boys of the same age. Up to fourteen years of age the endurance of the girls was found to be of greater extent and showed a greater percentage than that of the boys. At the age of fourteen, the work of the girls practically reached its maximum, and from there on up to twenty years of age, the limit of the examination did not increase, whereas the boys continued to increase continuously up to twenty, and not only increased but seemed to increase at a greater rate than it had previously. The amount of energy displayed by the girls of twenty was about half that exhibited by boys of a similar age. There was a marked differentiation in the sexes at this age. The endurance of a child in the lower grades was slight, but as the upper grades were reached it increased continuously until the endurance of the boy pupils in the higher grades amounted to about six times that of the poorest pupils.

Dr. Christopher exhibited an ergogram of a sprinter. This school-boy racer said he could run three hundred yards, but could not go three hundred and thirty yards. He exhibited a high degree of strength for a short time, when he suddenly broke to complete exhaustion in a less time than a normal child would break. Another ergogram of considerable interest was the one of a choreic child, which showed irregular elevations, irregular times, irregular spacings and, in general, was a perfect picture of the movements of chorea as are observed by the eye. This child presented an unusual amount of energy in its sum total, and continued the work on the ergogram for double the time most children could maintain it.

The paper presented a confirmation of the work done by Dr. W. Thompson Porter in the examination of school children in St. Louis in 1892. From his observations in St. Louis, Dr. Porter concluded that physical superiority was associated in school children in general with intellectual precocity, and that physical inferiority was associated with mental inferiority.

There were ten charts shown illustrating the physical peculiarities of the twelve-year-old children as they occurred in the different grades of the Chicago schools. Five hundred and three children were examined and many of them were found scattered through the grades from the second to the eighth year inclusive. The averages of the physical measurements of the pupils in each of these grades were taken and a curve drawn representing the averages in each

grade. It was shown that the weight of a child in the second grade was less than that of a child in the third grade. In general, the highest physical measurements of all kinds noted were found in the twelve-year-old child in a number of grades, while the twelve-year-old child in a lower grade presented a less average in each of the physical measurements noted. In the intermediate grades, these averages were distributed in a fairly even way.

The facts presented above go to show that physical superiority and intellectual superiority, as a rule, go together, and physical inferiority and mental inferiority are likewise, as a rule, found associated.

Dr. McDonald, of the Bureau of Education of Washington, stated that the paper was one of the most important investigations on children that has been presented. The amount of work required on such a paper as that of Dr. Christopher is only known to those who undertake original research of this nature. He has had some experience here in Washington measuring twenty thousand children and appreciated the great work accomplished by Dr. Christopher. It is curious that people of a great deal of intelligence will ask to what use this investigation may be put. It is amusing to note that, while expeditions can be fitted out at great expense to go to the North Pole, objections are at once raised if a few facts are obtained about children which are not immediately utile. The results are not always as practical as the people would want them to be and this creates an additional difficulty. He has noticed that there is a divergence as to boys and girls about the age of fourteen. The current theory is that girls are brighter and mature more early than do boys, but it would now appear that at fourteen years of age boys take the advance of girls; that is, boys mature earlier. It is also a curious fact that children born in summer are healthier, stronger and brighter than those born during the winter. He thinks it would be very interesting to work out the relation between the weight capacity and vital capacity. On this head there appears to be absolutely no facts, and this is true also in relation to strength and pain. It has been his experience that those who can grasp the most are the least sensitive to pain.

Dr. Yale said that application along these lines seems to be very interesting. Referring to the first four charts, he said that while a boy is growing tall, he is not growing healthy. He ails a little on his way and presently catches up. He will be beginning to grow in weight before he grows tough.

Dr. Fruitnight suggested that the medical profession should study more strenuously along this line than has been the case in the past. He was very much impressed in Dr. Christopher's paper. According to him, the rule of school-life seems to be reversed and that the child is kept at his desk when he should be in the play-ground, reaping the benefit of the sunshine, and an effort should be made to secure some reform in the administration of school matters. It would be beneficial to the children if they could enjoy the open air, say, between ten or eleven o'clock to half-past two. In other words, the school noon-hour should be prolonged.

Dr. Cotton thought too much importance can not be attached to this kind of work. The profession is now in the area of a careful study of the developmental period. He is particularly gratified and proud that a member of the American Pediatric Society should have given the time and shown the ability in this line of study. He believes that it will stimulate the men, especially those who are more or less associated with the developmental period of infancy and childhood, to add their mite from time to time to the accumulating mass of data. He is very much impressed by Dr. McDonald's remarks in regard to the want of appreciation on the part of the public as to the investigations along this line, whereas the public is keenly alert to the apparent advantage of investigation in commercial life, for instance. He asked for some light in regard to the period of greatest fatigue.

Dr. Christopher said that there is a period of diminished endurance from the fourth to the eighth grade, and the ergogram runs level instead of running up as it does in the other charts.

Dr. Churchill asked whether those children who show the greatest endurance on the ergogram stand highest in their class.

Dr. Christopher replied that individual cases had not been taken. The sexes were not separated because the combined number was too small at that age, but he would answer the question in the affirmative.

Dr. Chapin said he had reached some peculiar conclusions in studying the measurements of the thousand children measured in the New York Juvenile Asylum. First, the scheme of the measurements was made, then he had a report from the teachers as to the intellectuality of those children. It was shown by careful examination that some of the boys who were among the brightest had developed mental vices. In answer to a query, he said that the children were not normal.

In expressing his appreciation of Dr. Christopher's work, Dr. Ratchford said that he thought it had been probably carried on under better conditions than almost any other piece of work with which he was familiar. The results were most conclusive and reliable. He does not think the profession is in a position to interpret exactly what this ergogram means. His understanding is that it indicates muscle-fatigue as well as nerve-fatigue. It is difficult to explain why those who are weak and nervous should have been able to lift the required weight so many times. He thinks that it is of great value if it can be read to show nervous exhaustion in a child. The habit has been to attribute a great many nervous diseases to a strain from work. Referring to the chart on school life and sight, he thinks that the child from whom that chart was made was in a well-lighted and well-ventilated school, and that

the pupils were under the best hygienic condition. He thinks that the questions of school-life and hygiene have something to do with what has been written on the subject of school-life on sight, and it is probable that the sight may be impaired along with other things. There seems to be an actual basis toward precocity, and that in children of a common age the child having the best physical development is further advanced in school-life than weaker children; that is, he is capable of doing sustained work in the school.

In closing, Dr. Christopher said that an attempt had not been made to solve all problems. In the experiments at the Alcutt School, the average weight of a six-, eight- or nine-year-old child was not found to be greater or less after vacation, and there was so little information on this point, as to the liability of a child to increase in weight during vacation, that the matter was not reported. Some children improved, some did not improve, and some actually lost in weight. Some worked during vacation, some went out in the country, and some went into stores, and the statistics were thrown out as unsatisfactory. He referred to the fact that there is little discrimination on the part of teachers in reporting the condition of their pupils. The teacher's marking was thrown out as unreliable and it was necessary to go back to the line that the child's standing in grade indicated. The great standing in each number is certainly full of meaning in regard to intellectual capacity, because the grading is upon intellectual standing. There is more meaning in the grade standing than in the teacher's marking. Referring to the question of color-blindness among pupils, this defect has been found in rooms where the teacher asserted with great positiveness that no color-blindness existed at all, that the pupils used their colors perfectly in drawing and painting, and yet an actual test showed some of them to be distinctly color-blind in whole or in part.

Epidemic Paralysis in Children.—Dr. Henry D. Chapin of New York presented a paper in which he stated that in the case of a number of children who had paralysis it was due to poliomyelitis. It is probably due, he thinks, to some infectious agent. He dwelt quite exhaustively on the epidemic of paralysis which had occurred in Poughkeepsie, N. Y.

Atresia of the Larynx Due to Faulty Intubation.—Dr. Northrup, in his paper on this subject, stated that the fault in this case was due to the operator. A subsequent operation was performed but was not able to relieve the obstruction. The child died in November. Dr. Northrup exhibited the specimen and explained the case in detail. He stated that the child pulled out the obstruction several times, twice with a string, and in that way acquired a relaceration up to the number of five in all, until at last it could not be lifted. The larynx had been wounded at that time by some sudden accident and dyspnea set in.

Dr. Cotton, in discussion, asked whether the malformation of the larynx was natural or due to inflammation or disease.

In answer to Dr. Cotton's question Dr. Northrup said that it was the result of traumatism. He did not think it was possible for everybody to do intubation without detriment to the patient.

Head-Nodding and Head-Rotation in Rachitic Infants.—Dr. J. Milton Miller of Philadelphia, in presenting his paper, stated that the particularly interesting and peculiar nervous affection in young children, variously known as spasms nutans, gyrospasm, rotary-head spasm, head-nodding and head-jerking, and which is commonly associated with nystagmus, was his apology for presenting the three cases which had come under his notice during the past ten years. He regretted not having made a more thorough study of the eye-symptoms, admitting that he had not been as alive to the close and important relation which the symptoms bear to the etiology of the affection. The first case was that of a five-months-old colored boy who was first seen by him February 3, 1898. This child had been breast-fed but had never been well. He had always been subject to gastro-intestinal disorders. He suffered from abdominal pain, vomiting and obstinate constipation. The belly was protuberant and flaccid, the fontanelles large, and there were no teeth. The epiphyses of the wrist and ankles were enlarged and the ribs slightly bended. The child weighed at birth eight pounds, and ten pounds and fourteen ounces at the time the author saw him. By the use of massage, salt baths, cod-liver oil and artificial food, he improved somewhat. The child left the hospital and was brought back again because of peculiar movements of the head and eyes which had existed about six weeks. It seemed that these movements had followed an attack of measles some few months before and because of this illness was weaned entirely and fed upon cow's milk and Eskay's food. The evidences of rickets had markedly increased. The bowels were still obstinately constipated and the tongue coated. The head movements were vertical, that is up and down, occasionally somewhat lateral, with the inclination of the head to the right; it was not a spasmodic movement, occurring about ninety times a minute and ceasing only if the child was feeding.

The second case was that of a white female child, twelve months of age, breast-fed for three months and then fed on condensed milk. It was first seen at the Children's Hospital in February, 1895. The child had diarrhea and constipation alternating for many months and could not walk. There were very marked rachitic symptoms, protuberant belly, wide fontanelles, and no teeth. There were enlarged epiphyses and a well-defined rosary. The head movements had been noticed by the mother since the seventh month. They were lateral or rotary, rapid, smooth and rhythmical, occurring from fifty to sixty times a minute, and ceasing when she lay down. The pupils were equal and reacted to light; both knee-jerks were present.

The third case was a female infant, three months old, and had been fed upon condensed

milk since birth; the teeth were absent and there were many evidences of rickets. The tongue was coated and the child was subject to attacks of diarrhea. The lateral movements of the head lasted for two months and were only noticed when the child sat erect. There was no nystagmus. The treatment of all these cases consisted in regulation of the diet, salt baths, massage and the administration of cod-liver oil.

Poisoning by Vapo-Cresoline.—Dr. Samuel S. Adams reported two cases of vapo-cresoline poisoning which he thought were directly attributable to the fumes of a vapo-cresoline lamp. In both cases the poison was not suspected. In the first case he was told that the child had whooping-cough, and in the second case he was told by the doctor, by whom he was called into consultation, that the child was dying of pneumonia. In this latter case he found the child with stridulous respiration and it frequently cried; there were also present a cold, clammy sweat and dilated pupils. The family expected the child to die every moment. He stated that as he was leaving the room he saw between the crib and mother's bed a vapo-cresoline lamp. The history of the case was that the child had bronchitis and on the suggestion of someone the mother had secured a vapo-cresoline lamp which she had placed in the room the night before Dr. Adams was called in. About twelve o'clock that night the child refused food, which was at once remarked upon. It seemed to grow quiet, but at four o'clock the mother was awakened by a peculiar noise, and picking up the child found it in a cold sweat. Dr. Adams had the child removed to another room, where the windows had been raised and fresh air admitted. The child seemed to grow better, but when taken back into the sick room the symptoms reappeared, which indicated to him that the fumes from the vapo-cresoline lamp had caused the disorder. He stated that the odor of the vapo-cresoline lamp was apparent to his wife after he returned home. He reported these cases for the benefit of the Society.

The following papers were read by title: "Naso-Pharyngeal Disease in Pediatric Practice," Dr. F. Huber, New York; "Malarial Coma," Dr. G. M. Acker, Washington; "Pertussis," F. Forchheimer, Cincinnati; "General Subcutaneous Emphysema," Dr. A. C. Cotton, Chicago.

The following officers were elected at the business meeting preceding the morning session: President, Dr. Booker; Vice-President, Dr. Packard; Secretary, Dr. Morse; Treasurer, Dr. Adams; Editor and Recorder, Dr. Carr; Member of Council, Dr. Crandall.

Nigara Falls was decided upon as the next place of meeting, the sessions to be held May 27, 28, 29, 1901.

On motion of Dr. Samuel S. Adams, a vote of thanks was extended to the retiring President. The thanks of the Society were also extended to the Rector of St. John's Parish for the use of the hall, and to the various residents of Washington whose hospitality had been extended.

REVIEWS.

The Nature and the Work of Plants. An Introduction to the Study of Botany. By D. T. MacDougal, Ph.D., Director of the Laboratories, New York Botanical Garden. The Macmillan Company, New York.

Nature study has been much in vogue during the past few years, that part devoted to the study of plant-life being especially active. A large number of small manuals, founded to varying degrees on Kerner's "Life of Plants," have come in rapid succession. This, one of the latest, as well as one of the most elementary, is an excellent introduction to the living phenomena of plant-activity. We can cordially commend it to those desiring an authoritative and yet an elementary treatise.

A Dictionary of Terms used in Medicine and the Collateral Sciences. By Richard D. Hoblyn, M.A. Thirteenth Edition. Revised by John A. P. Prince, B.A., M.D. Lea Brothers & Co.: Philadelphia and New York.

We have been using this handy volume for some time and find it reliable and comparatively complete. As far as the terms of medicine are concerned, it contains most of them. Older methods of spelling are followed. In the matter of the words in vogue in the collateral sciences, like Mark Twain's Jumping Frog, we fail to find any particular point about that frog. Biological, chemical and botanical terms are few and far between and this dictionary has the same defects that all of them have in this line. Its medicine is, however, very good and there are a number of original features in the grouping of related topics that are strikingly suggestive.

THERAPEUTIC HINTS.

For Acute Pharyngitis.—

Apply wet compresses to the neck, give the patient small lumps of ice to hold in his mouth, and prescribe a mucilaginous gargle such as the following:

℞ Decoct. fol. altheæ (parts 1—10)...℥ vi
Tinct. opii.....mlxxv.
M. Sig. Gargle, to be warmed.

Another very useful gargle is a solution of 1 grain permanganate of potassium in a pint of water.—*v. Schrötter* (Landesmann).

Topical Application for Burns.—After having washed the part with boric solution and having evacuated the blisters if there are any, apply with the aid of a brush the following solution:

℞ Tannin.....℥iiss
Alcohol.....℥iiss
Sulphuric ether.....℥iiss.
M. External use.

M. Nikolsky (*Bull. gen. de Therapeutique*, March 8, 1900).

ORIGINAL ARTICLES.

THE STATUS OF GYNECOLOGY IN 1876 AND 1900.[1]

BY ALEX. J. C. SKENE, M.D.,
OF NEW YORK.

THE conception of modern gynecology began about seventy-five years ago when obstetricians discovered that woman was more than a mechanism for reproduction, and surgeons became fully aware that they had much to learn regarding her diseases and their treatment. This realization of the unknown awakened interest and gave a new impetus to the evolution of gynecology. Slowly, almost imperceptibly, learning advanced in this branch until thirty-five years ago, when, stimulated by the ever brightening light of modern medicine, the development and growth in this field became progressive to an amazing degree.

Twenty-five years ago the knowledge of this branch of medicine had grown sufficiently great to entitle gynecologists to a special position in the profession. At this time gynecology may be said to have graduated with honors and to have taken a well-merited position among the grand divisions of the profession. This graduation—so far as this country is concerned—took place at the advent of the American Gynecological Society, an occasion which lingers in the memory now as an inspiration and a benediction.

In 1876 gynecology appeared like a young and brilliant member of the medical profession, well versed in all that was known at that time, but not the mature expert, well trained by long experience—yet enthusiastic, and very anxious to push onward to new and higher attainments.

The literature of gynecology was immature then, but embodied all the best thought and definite knowledge of the age. There were altogether about three hundred printed books which contained the essence of all the science and art of gynecology that had been brought forth in the periodical literature and booklets in the preceding seventy-five years. There was one journal devoted to the subject and one gynecological society in existence and ten obstetrical journals that had gynecological departments. To speak figuratively, gynecology and its literature had passed the infantile period of existence and attained to the age of puberty with all the essential elements in its organization outlined by the developmental processes and surrounded with the nutritive conditions foreboding a phenomenally rapid growth and the promise of a speedy maturity.

The teaching in this department in the preceding days consisted of three or four lectures on diseases of women by the professor of obstetrics, an occasional reference to the subject by the surgeon, and, by way of clinical instruction, the student might be permitted to see the cervix uteri through a Ferguson speculum on several notable occasions. At the time now in review the obstetrician gave about a third of his time to diseases of women. Surgeons also taught some of the operations in gynecological surgery. Indeed, in some of the most advanced medical schools, here and elsewhere, a course of scholastic lectures was given which embraced all of the subject matter or science extant in the literature. Clinical teaching in the schools in general was rather meager still, although a few of the masters here and there gave practical instruction in all that was known twenty-five years ago. Clinical teaching, which was inaugurated in Italy at the beginning of the seventeenth century, made rapid progress and spread all over the scientific world until all branches of medicine were practically taught in an acceptable way in 1876—except gynecology which remained behind. There were many clinical orations on diseases of women given annually, but the practical drilling necessary to make competent practitioners hardly met the requirements.

The differentiation of sex was receiving due attention and the characteristics of woman in all her infinite variety of structure and functions and their relation to health and disease were well outlined in the minds of the foremost gynecologists. The relation of the reproductive system to the general organization had received liberal consideration. The scientific discoveries at this time paved the way for the emancipation of woman in her social, ethical, and political life about which philosophers and philanthropists have had so much to say in later times.

Anatomists had mastered the descriptive anatomy of the pelvic organs before the dawn of gynecology, and some needed information regarding surgical, regional, and transcendental anatomy had been added, so that the gynecologists understood those structures the diseases of which now claimed their attention.

The breath of scientists had blown away the mystical fog that had for ages hung around the function of menstruation. Now it was known to be conducted on the same principles as all other physical phenomena and more rational ideas were entertained regarding its utility in the economy. Still, the histology of the structures concerned, its advent at puberty, the physical necessity for it, the inducing conditions, the laws governing

[1] Read at the twenty-fifth annual meeting (Semi-Jubilee) of the American Gynecological Society, held at Washington, D. C., May 1, 2, 3, 1900.

and the beneficial results obtained by menstruation were being evolved, but not definitely settled.

The methods of observation and detecting organic diseases of the pelvic organs had caught up to physical diagnosis as practised in other branches of medicine and surgery. The instruments previously invented for facilitating inspection were not only useful for diagnosis, but made the procedures in plastic surgery possible—such, for example, as vesicovaginal fistula and injuries of the cervix uteri. In fact, this successful plastic surgery of the pelvic organs and ovariotomy were the triumphs which placed gynecology upon a plane of equality with general surgery.

Diseases of the uterus of the inflammatory and malnutrition order were known in a somewhat indefinite way. The inquisitive had looked beyond the "ulceration of the os uteri," postpartum subinvolution, and leucorrhea and had seen various morbid states, the pathological significance and classification of which were still rather chaotic. The problem of causation of these uterine diseases was being wrought out, but was not completely solved. Many factors, such as germ infection, had not been fully admitted to their proper place in etiology. Owing to this incomplete knowledge of pathology and etiology, uterine therapeutics were limited and somewhat incompetent. This was in keeping with the basic fact that rational treatment has not preceded, but has followed scientific pathology and etiology.

The normal position of the uterus in the pelvis and the physiological limits of its mobility had been comprehensively studied, and the structures which hold the uterus in place, having been investigated by a number of able observers, were about definitely agreed upon. Displacements of the uterus had been all fully described and the causes were still subject to discussion with a near approach to agreement. The treatment of these dislocations was still limited to mechanical means plus restoration of the pelvic floor. The net result was relief in many, recovery in a few, and failures to even help in a considerable number of these cases. Surgery had only played a small part in the treatment of uterine displacements. Pathologists had discovered at the postmortem table most of the malformations of the uterus arising from lesions of development. Some of these had been recognized clinically and some surgical work had been tried for their relief with results that encouraged farther efforts in that direction. Neoplasms of the uterus, such as myofibroma, carcinoma, and sarcoma, were well advanced so far as the natural history, pathology, and diagnosis were concerned; but the treatment of these was not far beyond the palliative stage with some suggestions or foreshadowing of great potentialities in surgical treatment. I refer to isolated efforts at extirpation of intrauterine fibroids, hysterectomy, vaginal and abdominal and high amputation of the cervix. Most of these operations were considered at that time to be daring experiments not sufficiently successful to be justifiable operations.

Inflammation of the pelvic areolar tissue and pelvic peritoneum still held a prominent position in the minds of gynecologists. Pelvic cellulitis especially was given the credit of being a very common affection by many, but the most advanced observers had begun to differentiate this affection from inflammation of the oviducts and ovaries, and some of the extremists went so far in that direction that they forgot cellulitis altogether. Obstetricians had noticed that pelvic cellulitis occasionally followed parturition, premature or at term, and they concluded that other pelvic inflammations presenting similar signs and symptoms must be cellulitis. At least, that is the only explanation at hand to account for the delay in getting away from the confusion and confounding of these diseases.

Pelvic hematocele maintained a prominent position in the classification of pelvic disease at this time, but notifications of ejectment were being served upon it to make room for ectopic gestation which then had come very impressively to the attention of gynecologists.

Ovariotomy was, no doubt, the most illustrious discovery in gynecology up to this time. The more heroic, competent, and progressive surgeons in this field pointed with justifiable pride to this means of eradicating the ovarian cystomata that heretofore had been fatal, crowding its victims out of existence by cruel and slow degrees. Confidence in the efficiency of ovariotomy as practised by the most experienced operators was fairly well established, not altogether on the results obtained, but on a growing comprehension of the causes of failure and an intelligent hope and prospect of overcoming the stumbling blocks in the way of complete success.

About this time the attention of all medical scientists was concentrated on bacteria and bacilli and the part played by all such germs in the causation of disease—especially sepsis in surgery. Ovariotomists were among the first to practically apply every germ of knowledge relating to aseptic and antiseptic surgery and were beginning to realize some advantages in their war against the infection of wounds in their special branch. A better knowledge of how to make hands, instruments and appliances cleaner, if not quite surgically clean, enabled the foremost of ovariotomists to escape from the dense clouds of carbolic spray that were presumed to purify the air, but at the same time poisoned, to a degree, the patient and operator. Post-operative septic diseases were still too common and hence the operators were obliged to struggle with the problem of cleanliness. Drainage of the abdominal cavity after ovariotomy was much in vogue then, and was of service in cases which had not been left quite clean and complete in all the necessary and possible conditions essential to recovery. The great advantages already attained in antibacteria methods gave a sense of security to the operators which was regarded by some so highly that they in some measure neglected the cultivation of dexterity and accuracy in operating and

lost ground to some slight degree just there. Taken altogether, ovariotomy was about the sum total of abdominal surgery successfully practised at that time, and was attended with an encouraging praiseworthy success in simple cases. There still remained much room for improvement in the management of complications and in cleanliness and technic generally. Toward these higher and better ends gynecologists were directing their efforts on scientific lines that had been fully laid out in this field of special surgery. Their energy, industry, and enthusiasm in this regard were most praiseworthy and deserving of success.

While the treatment of ovarian neoplasms was well on the road towards first place in the line of major operations, other diseases of the ovaries and oviducts were still in the hands of the student and clinical investigator. Acute and chronic inflammation of these structures had been discovered, mostly post-mortem, and their pathology described by the professors of morbid anatomy. Gynecologists were discussing the diagnosis, causation, and treatment of these diseases and two or three men had done some startling work in surgical treatment. Nevertheless, the whole matter had not been sufficiently elaborated to insure its unqualified acceptance as mature science and art by all who claimed kinship with gynecologists. If gynecologists left this part of their science and art a little behind, they certainly made up for it in after-times by rushing the matter forward until it threatened to overshadow all else.

Leaving out of account vesicovaginal fistula, vesical calculus, urethal caruncule and cystitis there was little known or said about diseases of the urinary organs in woman by any one anywhere, excepting in Austria where one man of brilliant mental capacity had brought up the subject to the plane then occupied by the other branches of this special department of medicine.

To present a picture that would represent the status of gynecology twenty-five years ago in anything near to a recognizable portrait, requires a bigger canvas, a brighter light, and far more of the painter's artistic skill than has come my way. However, I may borrow from the architect's method of representation and say that the ground to be occupied by the gynecology of the future had been well surveyed, the foundation of the structure had been built by most skilful workmen. The walls had been raised and roofed over. Halls, stairways, and rooms all outlined by framework and partition walls, and most, if not all, of the floors had been laid in mosaic of cubes from every known land. Several rooms were finished and furnished in modern fashion and fit to be occupied by the lords of this new creation. This structure had been named and declared to be worthy of a high place among the older and best mansions of the age. The designers and builders were acknowledged by the censors in medicine to be the masters of science and arts who held the full confidence of the profession.

There were few men at this time who gave their whole time and attention to gynecology and were known as experts or specialists in this branch of practice. There were, perhaps, two or three such in this country and about the same in other nations; a number who had a comprehensive grasp of this special practice with one hand, while with the other they still kept a less firm hold upon obstetrics, general medicine or surgery. All of them were noted, respected, admired, and honored for their honesty, earnestness of purpose, professional dignity, honor and courtesy among themselves and to all professional neighbors. Good natured, normal rivalry in the struggle for higher attainments in their science and art was at white heat, but uncontaminated by business or commercial methods of making a paying reputation.

Turning from this, glance backward upon the past to look at the present, the changes for the better and greater that appear are quite surprising.

The status of gynecology to-day is on a par with that of all other specialties in medicine. This, I presume, is admitted without reservation by all including a few of the obstetricians and general surgeons who claimed gynecology as their offspring which they may have hoped to keep to themselves for all time, that they might exercise a paternal and maternal control over it and share its honors and earnings.

This right and title of gynecology to live and maintain a degree of independence, being based upon its maturity and capability, has put to sleep all jealousy that may have existed and silenced the guns of the critics forever. This surely must be conceded by the most conservative when they witness the fact that to-day the literature of gynecology is as complete, comprehensive, and nearly, if not quite, as ample as that of any other special department of medicine. While there were only three journals and one society exclusively gynecological in 1876, there are now in every city and town the world over one or more journals and societies devoted to this new and youngest department in medicine. And the books have grown in number from 300 to 1000. Verily, the gynecologists have obeyed the injunction, "Be ye fruitful and multiply." In every medical school worthy of the name gynecology is taught by men of known ability. As much time is given to scholastic and clinical teaching as to any other subject, such as opthalmology and neurology; and professors of gynecology are many, perhaps a little supernumerous.

The mental and physical characteristics of woman and their adaptation to her cosmic relations, the interdependence and harmonious associations of her reproductive organs and general organization are now well understood. Consequently the etiology and diagnosis of diseases peculiar to woman are based on scientific principles, and the treatment is rational, not speculative. Along with this higher knowledge of the structure and functions came the comprehension of the

many derangements of the nutritive and nervous systems caused by diseases of the sexual organs which were called in the past hysteria, but are now known as reflexes and treated accordingly. In this matter much valuable aid has been given by the neurologists to whom due credit should be given. The inscription, which, freely, translated, means "The fellow is a woman because of a uterus," is seldom seen, but instead the present-day saying, "Men and women are equal, but not identical," is heard.

The physiological anatomy and histology of menstruation, the necessity for and cause of it, and the effect of its derangements upon the general economy are all well defined now and make a valuable part of the working capital of the practising gynecologists who have to care for the derangements of this function. The old order of therapeutics of a few years ago, emmenagogues for amenorrhea and astringents for menorrhagia with a liberal amount of gin for dysmenorrhea are forgotten. Puberty and the menopause, which were discussed in a few pages of some works on diseases of women, have been fully elaborated, so that now the latter is the subject of two books that are monuments to the industry of their authors and a benefaction to women.

The present status of methods of investigation and observation shows a marked improvement—or, rather, a growth in refinement and accuracy which is quite abreast of that of other departments of medicine.

The closure of vesicovaginal fistulæ and the repair of injuries of the pelvic floor, referred to as the top leaves of the tree of knowledge in pelvic surgery twenty-five years ago, have been supplanted by vast improvements in perineorrhaphy and many new surgical procedures which to-day fulfil nearly all requirements. Moreover, in the past there were few successful operators in this part of restorative surgery. Now they are plentiful as coal-tar products in the materia medica and many of them are competent.

All that was obscure and indefinite regarding inflammation of the uterus twenty-five years ago has been cleared away and now metritis in all forms, degrees, and varieties—with their septic, specific, traumatic and other causes—are all well known. Much light has lately been thrown upon all pelvic inflammations by investigations of the bacteria, native and foreign, found in the vagina and uterus, and, what is more pertinent at this time, many of these discoveries have been made by gynecologists. The causative relations of neoplasms and post-partum and menstrual subinvolution to metritis are settled questions. Clearer ideas regarding pathology and causation have led to more scientific treatment. The routine applications used in the past for all morbid conditions of the endometrium are forgotten. At this time all forms of uterine diseases are treated according to modern surgical and medical therapeutics which give results that might make the older gynecologists wish that their birth had been deferred a quarter of a century.

Equally strong lines and high light may be used in sketching the present status of displacements of the uterus. There is now more harmony of opinion regarding the normal position of the uterus, the agents which keep it there, the causes of displacements, and the structural changes in other pelvic organs and tissues which follow in the various degrees and forms of dislocations. Much as there is in this, it is little compared with the matured state of the treatment of uterine displacements. Mechanical support practised in the past, which generally relieved, sometimes cured, and often failed entirely, has largely been supplanted by a number of surgical procedures which, as practised at the present time, succeed in giving relief as often and as surely as failures occurred in the past.

Flexions of the uterus are closely related to displacements of the uterus, although many class them as malformations and treat them on that basis. Whatever opinions may be held regarding the pathology of these affections, their treatment is far in advance of that of the past. Incision and discussion of the cervix and dilation with that abomination, a sponge-tent, was the exclusive surgical treatment, but to-day the old has given way to new and vastly more satisfactory surgery. It may not be too much to say that the cure of a flexion of the uterus and its incident complications was an exceptional result of the treatment of that day, and now successful treatment is the rule.

Regarding for a moment neoplasms of the uterus, one has only to contrast the treatment of myofibromata in the past and present to be able to appreciate the extraordinary advancement. Pedunculated fibroids that had found their way into the vagina were removed and some of the leading operators had enucleated intra-uterine tumors, but not with encouraging results. This was about as far as surgery went in this direction. To-day the gynecologist, with his success in abdominal and vaginal myomectomy and hysterectomy, is now master of this field which he only entered twenty years ago. Similar, although less marked, is the reputation of the surgical treatment of cancers of the uterus at this time compared with the past.

Pelvic cellulitis is very rarely heard of now except as a puerperal disease resulting from some old-time obstetrical practice.

Pelvic peritonitis has also fallen from its high position to that of a secondary affection, having little interest compared to the preceding diseases which cause it. Pelvic hematocele also has been crowded almost entirely out of the mind of the gynecologist to make room for ectopic gestation to which so much profound consideration has been given, and for which so much is being done to save the victims of this strange blunder in reproduction.

Ovariotomy and bacteriology (in its relation to the causation of disease) were as school children, strong and prosperous for their age in 1876, and they have grown up together to a well-round-

ed maturity. The improvement in ovariotomy has been mostly in the direction of successfully dealing with all kinds of complications and notably intraligamentous cysts and injuries to the ureters and intestines. The making and closing of of the abdominal wounds and the protection of exposed tissues by the present methods of cleanliness in surgery have all been brought up to such a high plane of perfection that the only question remaining now is, shall the subject be handled with or without gloves?

The other diseases of the ovaries and oviducts, that were only known to the pathologists because they were generally incurable and often fatal, are now quite familiar to the gynecologist and as completely under his control as anything in his practise. Opening a pelvic abscess through the vagina was about all that the surgeon dared to do in the early days of gynecology. Now diseased tubes and ovaries are extirpated with a facility and certainty of success that surpass all that was ever dreamt of, or hoped for, by the prophets of early days. In fact, abdominal and vaginal ovarosalpingectomy are among the most valuable and highly prized procedures in this branch of surgery. The only question one hears discussed at this time is the relative advantages of the vaginal and abdominal avenues of approach to the field of operation in certain conditions.

Diseases of the urinary organs in women have lately claimed much needed attention which has placed the subject upon the same plane as that of the most highly cultivated branches of gynecology.

These brief, incomplete references to a few of the prominent features in the picture of gynecology at the present time may enable one to see the whole subject as it appears before the profession and the public to-day. The gynecology of twenty-five years ago was likened to a recent graduate, well versed in the rudiments and having clear impressions of the general subject, but having limited power of expression, knowing much of what should be done, but having little ability to do. Meantime impressions have been multiplied and executive ability has grown in proportion until now gynecology is great enough to hold its place among the specialties in medicine and big enough to monopolize the full capacity of any brain—even although a little above the average in size and activity. Referring to the architectural simile employed to represent the status of gynecology at the advent of this society, it may be said that the rooms in the structure that were empty are now fully furnished in a scientific and artistic style, embracing all the modern improvements. Plans have also been made for large additions in the way of hygienic and protective medicine.

Regarding the character and standing of gynecologists at the time when this imperfect little description began, it is true and well to say that there were giants and gentlemen then—learned, dignified, earnest men who were just, courteous, and observant of all that is best in professional ethics and etiquette, regarding always the rights of others as equal to their own. To-day gynecologists, both amateur and professional, are far greater in number, but evidently not superior in ethical culture and altruism. They may be better in this respect than they appear to be. Owing to overcrowding, the gynecologists in their struggle for a living may fail to respect their neighbors as they do themselves—although they may still have the inherent desire to do so although eyes that were used to the light of the past fail to see it.

These remarks are given from my memory of the past and my impressions of the present and are, therefore, incomplete and, to some extent, inaccurate. I had no time to give the names of the men who made gynecology and give credit to each for work well done. This, however, is not necessary in addressing you who know well to whom the honors are due.

Finally, an unbiased study of the part played by this country in the evolution and actual life of gynecology enables one to keenly feel, without a shadow of the arrogant or vainglorious that, in the discoveries, development, and growth of gynecology this country has been and is now first among the foremost—and this Society for the past quarter of a century has been and is now the representative of all that is indicated and comprehended in its name.

THE PHARMACOPŒIA OF NINETEEN HUNDRED.[1]

By HORATIO C. WOOD, M.D.,
OF PHILADELPHIA.

In the thought of the Infinite it may well be that in unbroken sequence event follows event from infinity to infinity, but man, bound to time by the limitations of his own existence, for his own purposes arbitrarily breaks the monotony of progress and calls the larger fragments years, decades, centuries. To-day the tally of the decades is full, and assembled here together we stand upon one of those great mounds which mark the passage of a century. Looking forward as a traveller who has reached some high dividing summit we strive to peer into the future, but its mists are impenetrable, and what seems to our straining vision the outlines of figures are but the projected shadows of the present. The view behind is plainer; the roads by which we have reached the summit are crowded with footsteps, in the near-by sharp and distinct, and fading with the distance. Under such circumstances it is but natural that the opening address of your President should take an historic tinge, and that before we settle down to work we should try to draw from the past such lessons for the present as shall make secure the future. Such retrospect is especially fitting since our labors, when they shall be carried to their end, will finish the first

[1] President's Address to the Committee of the Revision of the U. S. Pharmacopœia, Washington, D. C., May 2, 1900.

century of Pharmacopœial work in the United States.

It is true that, as told in the historical introduction to the Pharmacopœia, there was published in Philadelphia in 1778, for military purposes, a small Pharmacopœia; but it was the Counsellors of the Massachusetts Medical Society who, in 1805, first appreciated the need in America of a general Pharmacopœia; and it was the result of their labors, issued in 1808, that suggested to Dr. Lyman Spalding of New York City the formation of the National standard.

The dry-bones of history, such as may be found in the opening pages of the U. S. Pharmacopœia, interest most of us but little, but, when they are clothed with flesh and blood, it quickens heart-beats to see how near akin the men of the past were to the men of the present; and how, notwithstanding all change, the continuing brotherhood of the race reveals itself in the written lines.

In 1874, profoundly impressed with the rapid multiplication of medical books, and the phenomenal growth of medical literature, I wrote in opening the preface to my book on Therapeutics: "Indeed, art is so long, life is so short, that every student has the right to demand of an author by what authority he doeth these things, and to challenge every memoir for its *raison d'être.*"

Judge of my surprise, when recently looking over the Pharmacopœia published by the Massachusetts Medical Society, to read among the first sentences, "Books multiply so fast that it has become necessary to preface every new work with reasons, indeed, almost an apology, for its appearance." This in 1808, when America was little else than wilderness; when, as we view the matter, neither medical journalism nor medical literature existed in the United States.

Very far from the truth is Tennyson's antithesis between the permanence of the brook and the momentary life of humanity; the fact is that the stream of mankind "flows on forever" as much as does the current of the brook; only as the drops of water in the brook change moment by moment, so do the drops come and go in the great human stream; and almost as like as drops are to drops so is man to man. Hands from which had scarcely fallen the gauntlets of Puritanism, wrote in primeval New England, "It must not be understood that in adopting the modern language of botany and chemistry we have consulted the whims of every pretender. In this as in former ages men are creating confusion by creating names."

Wise words are these, which the coming Sub-Committee on Nomenclature of the U. S. Pharmacopœia should ponder a little more seriously than have their immediate predecessors. "In this as in preceding ages men are creating confusion by creating names." Applicable is this to all sciences, but most applicable is it in the purely natural history studies, so-called, such as zoology and botany. Smith, or Jones, or Thomson, or Cope, written at the end of the name of an animal or plant, fails not in its influence on human personality. I well remember with what glee and pride in the days of my callow youth, when I should have been under the taskmaster's learning methods and facts, I first saw H. C. Wood written after the name of a piece of fossil drift-wood from the coal fields of Pennsylvania. The boy is the father of the man. Unconsciously there remains in each of us some capacity of enjoyment such as was in the boy who, pointing to his name in the newspaper, said to his old aunt, "That's me." If the personal element could be withdrawn from the specific nomenclature of animal and plants there probably would be much simplification. Let it be said of none of us that we have created confusion by creating names. Why must the poisoned American perish while we are searching our memories for *ferri oxidum hydratum cum magnesia,* when *antidotum arsenici* might have saved his life if only he had lived in Germany?

In the preface of the Pharmacopœia of 1808 it is interesting to find the germs whose subsequent growth has cost the members of this Convention and its Committees so much labor. In accordance with the statement in the preface, "As there frequently arise errors of no small importance from the promiscuous use of weights and measures, it is proper that the quantities of substances, whether fluid or solid, be determined by weight." In accordance with this the framers of the first American Pharmacopœia adopted the system of parts by weight, but unfortunately they went on to say, "Yet it may suffice to measure wine, water and aqueous liquids in some instances, provided that for this purpose vessels be employed, of glass where the nature of the substance requires it, whose capacities and divisions accurately correspond with the divisions or multiples of the modern pound."

So saying, our fathers sowed the tares which grew up with the wheat, and choked out the true grain until only by the labors of many years were they up-rooted and the system of parts by weight in its purity reinstated in the U. S. Pharmacopœia. The tares grew rapidly, for in the second edition of the Pharmacopœia, that of 1820, fluid measures were employed. The sin of the men of 1820 in changing from parts by weight to liquid measures of quantity was made greater by the fact that the liquid measures were not at that time in use among the apothecaries of America. That the amblyopia of the revisers was not deeper than that of their contemporaries is, however, shown by the following extract from a contemporary review of the National Pharmacopœia in July, 1821: "If the American Pharmacopœia be adopted throughout the United States, as no doubt it will be, these modes of indicating quantities must necessarily come into use, and that they will be continued after having been introduced we do not hesitate to affirm, because they are more definite and precise, and consequently safer than the old methods. In such case it will be necessary that the

apothecaries be provided with the measures above mentioned."

The language of the Massachusetts Pharmacopœia of 1808 was English. The first United States Pharmacopœia of 1820 was printed in Latin, with a translation of the Latin into English upon the opposite page; and the Convention of 1830, in not departing from the use of Latin, justified itself in the language of the preface because "the Latin, if not essentially necessary, may prove highly serviceable by fixing the precise meaning of an English phrase which might not otherwise be well understood." Fancy an American apothecary or even an American doctor of the present time, when he could not understand the exact meaning of the English turning to the Latin to clarify his thoughts!

The Pharmacopœias of 1820 and 1830 were prepared by the Conventions themselves, these Conventions being composed solely of physicians. In 1840 the growth in numbers of the Convention necessitated the reference of the detailed work of Revision to a Committee, and the method still in vogue was inaugurated. The same Convention made itself further historic by the determining that the Convention to be called in 1850 should be composed of the two professions of Medicine and of Pharmacy, by whose co-union in labor the continuance of the Pharmacopœia of the United States as an authority has been made possible.

Since 1840 the great part of the labor revision of the Pharmacopœia has fallen upon the successive Chairmen of the Committee of Revision. In sixty years of these labors there have been only four, namely, George B. Wood, from 1840 to 1860; Franklin Bache, from 1860 to 1870; Joseph Carson, from 1870 to 1880; Charles Rice, from 1880 to 1900. As no revision of the Pharmacopœia has been more successful than the last, and as at no time have the necessary duties of the Chairman of the Committee been as great as they are at the present, so never in the century has there been found a man more laborious, more conscientious and painstaking, or better fitted by extraordinary acquirements and personal qualities to fulfil the onerous duties of the position than the present Chairman; and your President most earnestly hopes that by his continuance in office the success of the next revision of the Pharmacopœia may be ensured.

During its whole life the United States Pharmacopœia has received no governmental support, and has been free from governmental control. Under the circumstances the influence which it has exerted upon the pharmaceutical and medical professions and the voluntary obedience which has been given to it are not only a tribute to its practical excellence but also a strong evidence of that peculiar Anglo-Saxon power of recognizing authority which is not upon the statute books; a power born of self-control and common sense which makes the race of all others most capable of self-government. The indirect recognition by the Government of the Pharmacopœia becomes each year more apparent both in Federal and State legislature, so that there does not seem at present any danger of the Pharmacopœia losing its control in the United States.

The Pharmacopœias which have been produced in the United States by voluntary effort both in the past and in the present contrast favorably with the governmental standards of European countries. In its scientific accuracy, in its general usefulness and in the efficiency and elegance of its resulting preparations, our Pharmacopœia is the peer of the best. I am not one of those who are conceited in things American, freely acknowledging that we have added very little to the great sciences which underlie the practice of medicine, and that we have been indebted to Europe for almost all of our fundamental inspirations. I still hold most strongly to the belief that there are no therapeutics superior to the American therapeutics, and that in no country has pharmacy been carried to the perfection that it has reached in the United States.

Delegates of the Pharmaceutical Associations, I congratulate you on representing a profession which has attained its highest development in the United States.

There is a probably widespread, and certainly often spoken of, feeling that the medical profession of the United States does not properly appreciate and support the U. S. Pharmacopœia. There is some foundation for this feeling, but certainly it is exaggerated. It is true that—owing to the activity of manufacturing pharmacists and the number and skill of their commercial salesmen (vendors of samples), aided by the deficiencies of medical education and the peculiar childlike credulity which is so common in doctors—all kinds of proprietary mixtures and proprietary articles, and extra-pharmacopœial remedies are largely used in the United States. It is so easy for the lazy doctor to write for Smith's Panacea for Human Ills, and so easy for the doctor who knows neither Materia Medica nor Therapeutics to order Jones' Consumption Cure or Thomas' Kamiantia, that so long as laziness and incompetence remain with us so long will this thing be done. But this is no fault of the Pharmacopœia, and no perfection of the Pharmacopœia can greatly influence it.

Certainly any attempt to reduce the products of the Pharmacopœia to the level of the proprietary or patent medicine would be to destroy the dignity of the work, to bring it into contempt, and finally to uproot its influence. Under the influence of State law and of public opinion the average education of the American medical profession is rapidly and steadily rising; in this and not in anything that this Convention or its Committee can do lies the hope of the future. Moreover, the intensity of the feeling that the American medical profession is not as thoroughly interested in the Pharmacopœia as it ought to be rests largely upon a misconception of the intent of the Pharmacopœia, and its relations to the

medical profession. A Pharmacopœia is not intended to be a guide to practice, or a working-book to be used by the doctor, but is really the hand-book of the apothecary. I do not believe that at any time or in any country Pharmacopœias ever have had much sale among the medical profession; and each year, as the professions differentiate themselves more and more, as the doctor becomes less and less of a pharmacist, the tendency of the doctors to buy Pharmacopœias must grow less rather than more. The Pharmacopœia can only be popularized in the medical profession by making it a treatise on Therapeutics; in other words by causing it to cease to be a Pharmacopœia. So long as it is a Pharmacopœia it is the basis upon which text-books and Dispensatories are to be written; and it becomes through these treatises a guide to the medical profession. It remains the apothecary's *vade mecum*, with which in hand he does his work, and its sales must be chiefly among the apothecaries.

There may have been a time when the medical horizon was so narrow that the doctor had time to trouble himself as to how the druggists made laudanum, but at present the doctor has as much as he can do to store his mind with purely medical facts; he wants simply to know what laudanum does when he puts it into the patient, and he trusts the apothecary to give him laudanum when he calls for it.

Be these things as they may, it is certain that the present condition of the U. S. Pharmacopœia is one of great prosperity. The book itself ranks with the best of its predecessors or of foreign Pharmacopœias, representing all that was possible in 1890. Its hold upon the people of the United States is more firm than it ever was before. Its sales have far exceeded those of any previous edition, and for the first time in the history of this Association the treasury is overflowing. Indeed, so rich have we become that the greatest danger which threatens the Association is, to my thinking, surplus of revenue.

Standing on the Great Divide between the centuries, viewing the Past and the Present, what lesson can we draw that shall help us to make sure the Future? Is it not that we shall push straight out the old paths? For one hundred years they have been trodden by successive generations, who have found them sure roads to scientific advancement and practical success. Why should we depart from customs whose soundness has been time-proven?

It is a remarkable fact that during a century of successful life this Convention or Association has had no written fixed law for its government. Largely for this reason certain errors have grown up and received widespread adherence as to the nature and scope of this body. Thus, many persons are inclined to look upon each meeting of the Convention as a separate and distinct Association, and even to consider the Committee of Revision as an independent body. The fact is that the Convention for the Revision of the United States Pharmacopœia is a continuing Association, parallel in its nature to the American Medical or the American Pharmaceutical Association, or other similar organization, the sole difference being that the period between its meetings is ten years instead of one year, as is usual. The Convention should really be spoken of as an Association; it is continually alive through its officers, whose duties never cease and whose positions are never vacant unless it be for the moment of change of occupants during the session of the Convention. The Convention is further always active through its Executive Committee and Committees of Revision and Publication, so-called, to which, as agent, the Convention delegates its powers when not in session.

The growth of this Association in numbers, in influence, and in wealth, has seemed to me to make it imperative at this time that what has been tradition and the growth of custom should be clothed with the fixedness and authority of written law, and that a written Constitution and By-Laws should be adopted.

The growing responsibilities of ownership and of business make it further essential that this body shall in some form or other be incorporated. It seems to me also necessary that a slight alteration should be made in our working methods; an alteration which is, however, not so much a change as a development. The present Committee of Revision and Publication has, as its name implies, two offices or functions which are entirely distinct; the one being concerned with the preparation of the Pharmacopœia, the other with its publication; the one requiring on the part of the Committee that has charge of it scientific knowledge and practical skill in medical and pharmaceutical matters, the other business judgment and activity.

It is certain that a scientist may also be a business man, but the scientist is in reality no more frequently a business man than the business man is a scientist; and so it has come to pass that in order that its personnel shall include men of business, of science, of medicine, and of practical pharmacy, the Committee of Revision and Publication has been composed of twenty-five members, a number which makes it cumbersome, wastes the time of the Chairman, and achieves results no better than would be obtained with much less labor by a smaller body.

The proposition which I have to offer for the consideration of this Convention is that this double Committee shall be divided into its component parts, and that out of it shall be made two Committees, one to prepare, the other to publish, the Pharmacopœia. Let the new Committee of Revision be composed of twenty members, and let the Convention nominate five members, who, with the President of the Convention and the Chairman of the Committee of Revision, after they shall have been appointed, shall constitute a Board of Trustees which shall have charge of the financial and publishing business of the Convention.

The experience of the last decade seems to make this imperative. A considerable sum of money has been very properly spent in the paying of experts for research work, but there are many members of the Committee of Revision who have done work greater in quantity and in importance than any of these investigators, who yet have received no compensation for their services. Why? Because gentlemen do not vote money to themselves out of public funds, even though it may have been properly earned.

Let me give you a concrete instance. Professor Maisch went over all the Materia Medica definitions of the Pharmacopœia; with his great knowledge and with a splendid Materia Medica Museum at his command he spent hours and days rectifying, enlarging, and perfecting the definitions of drugs until probably they are the best ever written; for which no compensation has been awarded him or his heirs. One of the duties of this Convention certainly is to set aside or in some way make provision for the payment of such services, but it is always better to be just during the time of action than to atone afterwards for an injustice; and if a Business Committee is formed by this Association it can determine the relation between the value of services rendered by the members of the Committee of Revision and the power of the Convention to compensate. If it be thought desirable, this Business Committee or Board of Trustees may be made to constitute, with the officers of the Convention and the Committee, a general Council, who shall represent the Convention in large matters, such as the decision of whether an extra edition of the Pharmacopœia shall be published in 1905, or whether in some emergency the Convention should be reconvened.

Time is failing, but I think it must be evident to everyone without further discussion that it is essential to separate that which is business and financial from that which is scientific and practical pharmacy; and that this Convention can best attain this object by having two distinct Committees.

Having adopted Constitution and By-Laws, appointed officers and the two Committees, this Convention should give instruction to the officers and the two Committees together to incorporate the Convention. I am told by eminent counsel that there is no legal difficulty in the way, only it must be clearly stated in the Constitution that a delegate from one of the bodies entitled under the Constitution to representation becomes by virtue of his election as a delegate a member of the incorporated body, and loses his membership when he ceases to be a delegate.

Finally, gentlemen of this Convention, a word and I have finished. As the American nation of 1800 seems to us to have been but a handful of seed from whose growth we are the fruit, so will those who meet here in the year two thousand think of the American people of to-day as a small body from which they have themselves sprung. We live but for the moment; one hundred years from now only the greatest of us will remain as fading memories; as men whose records have been so over-written on the palimpsest of time that only here and there can a sentence be deciphered. So it ever has been and so it ever shall be with the human race; men come and go and are not; but though the worker disappears and is forgotten the work lives on. Our fathers labored and we have entered into their labors. Let us see to it that preserving in its essential lines that which has come to us, and adding to it in our day and generation as strength is given us, we may leave for the coming century good work and true, which shall remain as the abiding though unrecognized witness of our earnest living.

THE TREATMENT OF SUPPURATIVE OTITIS MEDIA IN YOUNG CHILDREN.*

By GEORGE L. RICHARDS, M.D.,
OF FALL RIVER, MASS.;
OTOLOGIST AND LARYNGOLOGIST TO THE FALL RIVER AND EMERGENCY HOSPITALS; FELLOW OF THE AMERICAN LARYNGOLOGICAL, RHINOLOGICAL AND OTOLOGICAL SOCIETY, ETC.

This subject is presented in order to bring about the discussion of an important pathologic condition and not because I myself have anything especially new or novel to offer in the way of its treatment. From my own experience I am convinced that the average practitioner does not yet sufficiently realize the possible dangers to the child which lie in a suppurative ear. If he did there would not be as many suppurative ears in young children, which starting as acute conditions, become chronic and last weeks, months and years.

That their number is very large it is needless before this Society to attempt to prove; our personal experience is proof sufficient. I think we shall also be as ready to agree that they are frequently overlooked. Rasch[1] reports from the hospital in Copenhagen that in 61 necropsies evidences of otitis media were found in 61 of the children; of this number 32 had true abscesses in both ears. Ponfick[2] reports that in 100 consecutive autopsies of children dying from various diseases, the ears of only 9 per cent. were normal; in the remaining 91 per cent. a well marked otitis media of a purulent or muco-purulent character was present. While these statistics are those of foundling hospitals, where the children frequently are, or have been poorly nourished, and are not, therefore, to be compared absolutely with the statistics which would follow from an equal number of children taken from an ordinary community, they nevertheless show that otitis media purulenta is very common and is not estimated at its true importance. The recent valuable paper of Pomeroy[3] shows how possible and even easy it is to overlook acute otitis media in the young child previous to the time of any discharge. In many of these cases the objective symptoms

*A paper presented to the American Laryngological, Rhinological and Otological Society (Eastern Section) at its annual meeting in Philadelphia, February 17, 1900.

pointing to the ear are but few, and frequently vague or entirely masked. Even after suppuration is apparent the condition is frequently either entirely overlooked (and this was the fact in many of the cases the statistics of which I have quoted), made light of, or dismissed with the injunction to the parent to keep the child's ears clean.

Those of us who see a good many of these cases know how effectively the cleaning process is carried out. Usually it is a complete failure. We have all examined the ears that the mother tells us have just been cleansed only to find in the canal or tympanic cavity, or both, pus of so foul an odor as to be unbearable to any self-respecting nostril.

The causes of these suppurating ears in young children are various, but may be fairly easily classified into those dependent on the exanthemata and other contagious diseases; those dependent on positive pathologic processes in the pharynx and nasopharynx, as adenoids and enlarged tonsils; those dependent on the extension of catarrhal processes of the nose and nasopharynx, and those due to colds and exposure, starting as a simple acute otitis media of local origin. The child goes through the stages of an acute or sub-acute otitis, with earache, deafness and other symptoms belonging to the condition, followed by a discharge, at first serous, then sero-purulent and finally purulent. With the cessation of pain the matter is frequently forgotten by both physician and parent, and sometimes the physician's attention is not called to the case at all. When it is, some very vague directions are given as to the necessity of keeping the ear clean. The cleaning process is attempted, but the discharge continuing, becoming foul and the child being increasingly deaf, the specialist's aid is after a longer or shorter time sought. The ear is then thoroughly cleansed and appropriate treatment instituted, which, if carried out systematically, usually produces rapid and brilliant results; although it is also true that in the occasional case the suppuration continues in spite of our best endeavors, and before a cure is effected the aid of more radical surgery has to be invoked. To be effective the treatment must be frequent and the tympanic cavity kept free from any accumulation of pus and micro-organisms.

How is this to be brought about? All must have felt, as I have felt, the inability of the mother to bring the child to the physician's office for the daily treatment, not only on account of the expense, but also because of the trouble of taking the child daily to the office, to say nothing of the time consumed. Any one who has ever waited from one to three hours, in the office of some busy physician, for his or her turn knows that this question of the time consumed has its weight. How, then, can we teach the mothers or nurses of our patients so that they can intelligently care for the ear, whose treatment we have begun, and properly assist in the endeavor to restore it to health?

Premising that I am now chiefly concerned with the *strictly local treatment* of suppurative otitis, although in each case regarding the constitutional treatment as of the greatest importance, always to be carefully looked after and appropriate measures instituted, I will outline the method I am in the habit of using, which varies a little according to the length of time the suppuration has lasted and the degree of damage which the ear has already sustained. If the suppuration has lasted some time, the discharge very foul and caries of the tympanic structures already marked, I syringe the ear thoroughly with warm sterile water or with a solution of 1 to 5000 bichloride of mercury until all debris has been removed. The canal is then carefully dried and the ear inspected. If there is much destruction of the tympanic membrane, I apply peroxide of hydrogen on a cotton pledget (never dropped in) as long as there is any exudation of gas, and after again drying the parts, apply on a cotton pledget a saturated solution of boracic acid in from forty to ninety per cent. of alcohol, the percentage of the alcohol depending on the age of the child and the ability to bear the pain of the alcohol. In young children I seldom use over fifty per cent. alcohol. I next dust the whole surface *lightly* with powdered boracic acid or some similarly acting powder; of late I have been using boric acid and acetanilid with good results, also at times aristol, acetanilid, or europhen combined with stearate of zinc. These are all drying powders and I regard them as very useful, although some object to the use of powders at all. A powder can, however, be used with perfect safety in the ear if care is taken not to use too much and the powder is free from lumps. Lastly, I lightly stopper the ear with a small narrow wick of iodoform or other antiseptic gauze, taking care that the gauze reaches to the bottom of the canal.

If the process is more acute and the perforation small neither the peroxide of hydrogen, nor the boric-acid alcohol, nor the powder is used; but simply as thorough cleansing as possible through an opening in the drum membrane large enough to ensure drainage, with the insertion of gauze-wicking or cotton pledgets frequently changed in the manner to be described. If there is the slightest doubt as to the opening being large enough, a free incision is made at the posterior inferior quadrant of the drum membrane. This will often be found advantageous even when drainage is apparently good.

The office treatment is now apparently ended but the most important thing is yet to come, namely, the instruction of the mother or the attendant in the home treatment. This I regard as important as, if not more so than, my own and without which my endeavors are very likely to fail. With the aid of a diagram I show the mother a little of the anatomy of the ear, explaining that the floor of the middle-ear cavity is lower than the external outlet and that consequently natural drainage must of necessity be very poor. I tell her that drainage is what is wanted and

that it is absolutely essential, inasmuch as the matter retained in the ear is very destructive and is liable to produce permanent deafness or even death from extension to the neighboring regions of the brain and the mastoid process; and not infrequently I show her on a temporal bone how close the floor of the brain is to the roof of the tympanic cavity. I explain the necessity of keeping the ear clean, clear to the bottom of the tympanic cavity and show her that the wad of cotton which she had stuffed into the ear when she came serves only to retain the secretions, while being absolutely worthless as far as any drainage is concerned; that in effect it as completely locks up the secretions as though a cork had been inserted. She is now ready to receive directions for the home treatment and sufficiently interested and impressed to try and follow instructions to the letter. While I much prefer gauze drainage to any other, where it can be properly inserted, I do not as a rule order it for the average case simply because it is impossible to properly place gauze wicking in the ear without a suitable forceps and under fairly good illumination, neither of which conditions are apt to obtain in the home.

I take a knitting needle with the ends roughened by a file and carefully show the mother how to loosely but firmly wind a piece of cotton on the same with the end projecting a quarter to half an inch beyond the needle tip, far enough so that no harm can come to the ear from its use when gently inserted. A tapering wooden toothpick or any long, slender object with roughened surface will answer as well. To avoid the slightest possibility of doing any damage with the applicator I instruct the mother to hold the applicator so that it can not possibly be pushed into the ear beyond a safe distance and show her what this distance is. Taking the child before a good light I illustrate how drawing the cartilage of the ear backward straightens the canal, and show her how to insert this cotton pledget to the bottom of the canal, warning her against the most frequent cause of failure, the taking of too large a piece. I tell her on the following day, or as soon as the wick put in by me is soaked through, that she is to withdraw it and then wipe out the canal way to the bottom, as taught. This is continued with fresh pledgets until the tip of the pledget is no longer moist. She is then instructed to take as much of the powder ordered for her as will go on the tip of a small penknife and, through a bit of rubber or glass tubing, blow the same into the ear. If the perforation is a good-sized one and considerable caries is present, I frequently have the boracic-acid alcohol drops also used at home. Finally, the mother inserts a small narrow pledget deep in the ear and withdrawing her needle with a backward twisting motion leaves the cotton in the ear. As, unlike the wicking, this will not withdraw the fluid with as ready capillarity, I order this procedure done from one to three times a day, according to the severity and activity of the process present and direct that the child be brought to me in from three to seven days. No home syringing is allowed in this method and I am certain that the results are more rapid and satisfactory than when I directed that home syringing be done, although I know that men of much larger experience than myself advise the frequent use of the syringe and regard the method I have outlined as unsatisfactory. In my experience home syringing is seldom satisfactorily done, nor is the canal properly dried afterward; and if not dried thoroughly the remaining fluid is a damage rather than an advantage since it favors the more rapid growth of micro-organisms. Again, the syringe used is frequently not a proper one for the purpose, nor can the very poor always buy the right kind of syringe.

Be that as it may, the method here outlined, when carried out in all its details, is applicable to rich and poor alike and is productive of good results; the details are essential to its success. In a word, cleanse and treat the ear yourself as may be necessary and have that treatment made efficient by the aid of thorough home treatment. I may add that I treat all discharging ears on about the same principle, acute as well as chronic, the details varying with the degree of involvement of tympanic structures and the amount and character of the discharge; as before stated, the peroxide, boracic-acid alcohol and powder being omitted in the acute cases.

Nothing here mentioned is to be considered as opposed to such operative measures as may be needed for the correction of nasal, nasopharyngeal, or pharyngeal conditions which are causative or contributory. These should receive early attention. The more chronic cases and those with complications, as cholesteatomata and marked destruction of the ossicles, will have to be directly considered from the operative standpoint. Even these cases are frequently susceptible of great improvement when treated as I have indicated, and those refusing operation so much benefited as to apparently make an operation seem to be unnecessary.

After several years' observation of a large number of cases I am opposed to much syringing in running ears, whether acute or chronic. It is at times necessary and no doubt there are cases where the syringing produces more rapid results than the dry treatment; I prefer, however, in the main the dry method. I would teach this method in all its details if it were possible to every practitioner, and when a running ear comes under his observation would have him teach mother or nurse how to keep it drained. I prefer gauze drainage, changed as often as soaked through, where skilled supervision can be had, but where it cannot, and these are the great majority of all cases seen by us, I believe that any fairly intelligent person with no more armamentarium than some absorbent cotton and an applicator, either knitting-needle, tooth-pick or something similar, and some antiseptic powder, and this last is not absolutely necessary, can keep

any suppurating ear nearly, if not quite, clean. In most cases the discharge will rapidly subside and many an ear may be saved. Wherever there is discharge of fluid from the ear, what is wanted is drainage. Whatever method will best bring that about is the best treatment.

It may be asked what is to be done with the unruly child, the child who will not allow its ear to be treated? I can only answer by remarking that it all depends on how the parents look at the matter. If the permanent well-being of the child is to take precedence over his present wishes then a way can be found to follow out the instructions given. Most children, after finding that the procedure is not a painful one, will readily permit it without making much fuss. The exceptional child must be held. With the aid of a second person, who will hold the child's head firmly against the side of the body, the other person can do the dressing readily enough. The arm thrown around the head will hold it firmly, whereas attempts to hold a child's head by putting one hand in front and one behind are generally failures.

CLINICAL LECTURE.

FIBROID TUMOR OF UTERUS; ENTEROPTOSIS; RETROVERSION; RUPTURED PERINEUM—OPERATIONS—RECOVERY.

By MATTHEW D. MANN, A.M., M.D.,
OF BUFFALO;
PROFESSOR OF OBSTETRICS AND GYNECOLOGY IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF BUFFALO; GYNECOLOGIST TO THE BUFFALO GENERAL HOSPITAL.

Fibroid Tumor of Uterus.—This patient is fifty-one years of age; married; has seven children, the last born fourteen years ago. She has had the trouble of which she complains for about a year. The symptoms are, first, flowing, which is at times very severe, clots sometimes passing. As a general thing she uses five napkins in twenty-four hours, which is the mark of rather hard flowing. The flowing is worse some days than others. Sometimes it lasts a week; this summer it continued steadily for two months. She is flowing less since she entered the hospital.

The next symptom is pain in the back and in the groins, especially on the right side. She cannot exercise because it "hurts" her. She gets out of breath easily, as in walking up stairs. Some days she is troubled by having to pass water too frequently; she often has to get up during the night for this purpose. Her bowels are constipated, and laxatives are a necessity. The patient has good color, is not thin, but looks quite robust. However, in these cases of pelvic trouble appearances are apt to be deceptive, so that one can rarely tell much from the expression and general looks of such a patient. From what she tells us, we are led to suspect that one of four different conditions may be present, *viz.*, fibroid tumor, carcinoma, endometritis, or mucous polypus.

Her flowing is *not* due, by the way, to the approach of the menopause as some of you may think. The menopause is the normal cessation of menstruation; it is not a disease, but a physiological process. It is a very common error to conclude that, because a woman's menopause is approaching, she will flow more than usual. The opposite should be the case. But a woman with some disease of the uterus which produces flowing will be apt to flow more at this time. Thus we have four conditions which may, under these circumstances, produce the symptoms of which the patient complains, a fibroid growth, a malignant growth, a polyp (and polypi occur very frequently at this period of life) or an endometritis. How can we decide between the four? The only sure way is by examination. When I made my examination I found that she had a tumor, probably as large as a baby's head, to the right side rather than to the left. This is firmly attached to the uterus and not tender. It presents all the evidences of a fibroid growth.

Suppose there were no fibroid and no disease of the cervix, and we wanted to determine if there were cancer of the body. We would curette the uterus and have the scrapings examined under the microscope. We could then differentiate between a malignant growth and an endometritis. If we do not find evidences of endometritis or of carcinoma, we can decide if it be a polyp by passing the finger into the uterus and simply feeling the growth, first, if necessary, dilating the cervix. This exploration of the interior of the uterus is too important to be neglected in doubtful cases. This woman has a fibroid. I want to determine if she can bear an operation. She is still flowing, which renders her rather anemic. She is weak; gets out of breath easily; her pulse is rapid, about 90; it sometimes drops to 80 or less, and then again rises to 90 or more. Another point of importance to be considered in deciding the question of operation is the condition of the urine. When she came here the amount was small, of low specific gravity, 1014, and contained traces of albumin, a few leucocytes, blood-cells, and epithelial cells. The albumin and the small quantity of urine secreted made us think it best to treat her for a while preparatory to giving her an anesthetic. With albumin in the urine, it is necessary before a long operation to get the kidneys into a healthy condition. Hence she has been given the treatment usual in such cases, daily hot-air baths, alkalies, and plenty of water to drink, combined with tonics. In two weeks her urinary secretion has increased markedly in amount; its specific gravity is higher, 1020; the albumin is diminished, although there is still a faint trace of it; her heart is better, and her gen-

eral health is improved; so I think I can safely operate in a few days.

The patient, being fifty-five years old, should have had the change of life some time since, but, as is so often the case in women with fibroids, it has held off. If it should come, she might be relieved of all her symptoms without operation. She is anxious to have an operation and I shall do a hysterectomy, operating through the abdomen, as the tumor is too large to take out easily by the vagina. The results in these cases are almost always satisfactory. In this case I think the patient will have the best chance if we anesthetize her with chloroform. Very likely I shall decide to begin with ether and to continue the anesthetization after a few minutes, with chloroform. Most of the deaths from chloroform occur in the stage of excitement during the first two or three minutes; and the injury to the kidneys from ether comes from its long-continued use. Thus both risks are diminished by giving the ether for a short time first, and then going on with chloroform.[1]

Enteroptosis; Retroversion; Ruptured Perineum.—The second patient is forty years old, and the mother of five children, having also had three miscarriages. The forceps have always been used at the birth of her children. She has been ill for the last two years. Her principal symptoms are dragging and bearing-down pains, pain across the back, and in the top of her head. She is dizzy at times and sometimes falls down unconscious. She is troubled with palpitation. Her monthly periods have been disturbed for the last two years. They are anticipated each time by a slight flow, which lasts four or five days. Four months ago the flow lasted a month. It has never been excessive in amount, rather scanty than otherwise, but has increased during her illness. Her digestion is faulty, and for the last four weeks has been worse.

A careful examination of the abdomen reveals quite a serious state of affairs. There is a general falling-down of all the abdominal viscera. The kidney on the right side is loose, falling almost to the pelvis, and is very tender. The transverse colon is greatly prolapsed. It is very commonly displaced. I find it below the umbilicus in probably fifty per cent. of the cases upon which I perform abdominal section. The vaginal examination also shows various affections of the pelvis viscera. I find a ruptured perineum, a badly lacerated cervix, retroversion of the uterus, with induration and hardening around the cervix due to the laceration. It is difficult to say what was the starting-point of the patient's troubles, but they probably followed confinement and the lacerations. The heart symptoms, the digestive disorder, etc., are all functional. There is no organic trouble with the heart; the pulse is good. There is a great quantity of pus in her urine, although the amount of urine is fair, and the specific gravity about normal. There is a faint trace of albumin so I shall have her anesthetized with chloroform instead of ether.

I propose this morning to curette the uterus, close the perineum, and repair the cervix, and perhaps do Alexander's operation. It is possible I may fasten up the displaced kidney.[1] In one case I did seven operations at one sitting; I curetted the uterus, closed the cervix, sewed up the anterior vaginal wall, repaired the perineum, opened the abdomen, removed a fibroid growth, and sewed the uterus up to the anterior abdominal wall. To have done one operation at a time and waited for the patient to get well before doing the next, would have kept her in the hospital five or six months. As it was, she was out in less than a month. The sewing-up of the kidney is not, of course, a strictly gynecological operation, but, as it was largely advocated by the gynecological surgeons, it has come to be considered a part of their work.

[1] This patient was operated on successfully, and returned to her home in three and one-half weeks.

[1] Operations on the endometrium, the anterior vaginal wall, cervix, perineum, kidney and round ligaments were done at one sitting, with perfect recovery.

MEDICAL PROGRESS.

Sympathetic Ophthalmia.—Gifford (*Annals of Ophthal.*, Vol. IX., No. 1) relates the histories of two cases of sympathetic inflammation following a perforating injury in the first eye, and one mild case following a cataract extraction. By medicinal treatment, together with enucleation of the injured eye, he was successful in retaining useful vision in the sympathizing eye in all the cases. In all there was an absence of the premonitary symptoms, such as photophobia, ciliary injection and asthenopia, which, according to the text-books, are warnings of danger. In fact, these signs of sympathetic irritation are rarely followed by true inflammation. In the three cases reported the uninjured eye felt perfectly well up to the time when the appearance of inflammatory products showed that the inflammation was present and under way to such an extent that even enucleation of the injured eye did not stay its progress. A point of the utmost importance for the early recognition of the disease, particularly when the patient is not under the constant observation of an ophthalmologist, is the performance daily of tests of the acuteness of vision. Gifford has treated earlier cases with atropine, hot applications and mercurial inunctions, in the usual way, without perceptible benefit. The later cases were treated with salicylate of soda, which in one instance was increased to 180 grains in the twenty-four hours. The results obtained by this treatment were very good. It is still an open question whether the inflammation reaches the second eye through the medium of the optic-nerve trunk and chiasm, as first suggested by Arlt, or possibly by Mackenzie, whose expression on this point was ambiguous; or through the intervaginal and subdural spaces, as suggested by Leber and Deutschmann; or along the vessels

penetrating the eye and passing through the orbit to the cranial cavity, as first suggested by Gifford, and later by Gaget; or through the general circulation, as suggested by Berlin.

Intubation of the Larynx.—In a series of seventy-five cases of laryngeal stenosis, in which he has employed the operation of intubation of the larynx, J. W. West (*Am. Gyn. and Obstet. Jour.*, April, 1900) has had a mortality of 43⅓ per cent., thirty-four of the seventy-five cases having died. The ages of the cases ranged from four months to sixty-two years. He presents a table showing the ages of the cases, the number at each age, and the mortality at each age. Out of five cases under two years of age, three recovered. In thirteen cases seven years old only five cases recovered, but of the eight which died, one died from an organic heart lesion, and two from profound diphtheritic poisoning. In the two last cases the intubation was done simply to relieve the dyspnea during the few hours of life which remained. In one case the obstruction causing the dyspnea was due to erysipelas. In two cases the dyspnea was due to laryngitis following an acute attack of measles, and the other seventy-three were cases of laryngeal diphtheria. Of the two cases following measles, one died. In the one which recovered it was found necessary to wear the tube for two weeks. The youngest patients to recover were two, each thirteen months old, and one fourteen months. The writer presents brief notes of three of the cases, and without describing the technic of the operation, emphasizes the fact that the manipulation must be done as quickly as possible, and that the erect position of the patient is most favorable to a rapid introduction of the tube. Care must be taken not to bruise or wound any of the tissues during the operation. The average time of leaving the tube in position in the cases that recovered was six days. When the dyspnea occurs at or near the onset of the disease it is usually necessary to keep the tube in position longer than in cases in which it occurs later. Intubation should be resorted to without delay when antitoxin and other remedies have failed to bring about speedy relief from dyspnea.

Treatment of Gonorrheal Epididymitis.—A. Spiegelhauer (*Monatshft. f. prak. Dermatolog.*, April 15, 1900) applies hot aluminum-acetate solution three times daily to the testicle which he supports by means of a firmly-fitting suspensory. The internal treatment consists in the use of sodium salicylate. This method is said to yield much better results than the time-honored cold applications.

Thoracentesis.—The time for removing the fluid from the chest in pleurisy with effusion depends more on the condition of the circulation and respiration than on the physical signs, says H. Desplato (*Jour. des Sc. méd. de Lille*, April 7, 1900). During the first two or three weeks tapping should be avoided unless the fluid accumulates rapidly, or the patient has attacks of dyspnea without apparent cause, or is short of breath on exertion. If the fluid has ceased to accumulate, draw off a part or all and use active purgation, and the disease will be much shortened. The liquid should be withdrawn slowly to allow time for the lung to unfold itself and for the other organs to accommodate themselves to the changed intrathoracic pressure. Accidents are due either to passing the trocar into lung, liver, a tumor, etc., a mishap which should easily be avoided, or to the diminution of the intrathoracic tension, causing cough, albuminous expectoration, hemoptysis, pain and dyspnea. The object of thoracentesis is to permit the lung to expand. If the lung is bound down by adhesions, or is the seat of a pneumonia, or a tuberculous infiltration or a tumor, if it contains cavities, or is emphysematous, or for any other reason has lost its elasticity, it cannot expand, and the negative pressure only serves to increase the difficulty of respiration. Not more than 1200 c.c. should be removed at one time; this is always enough to relieve the urgent symptoms and often allows the rest of the fluid to be rapidly absorbed. If necessary the tapping may be repeated in two or three days. A valuable adjunct to the thoracentesis is massage of the thorax, as this promotes the blood and lymph circulation and stirs up reactionary phenomena in the pleura. Electricity also by acting on the muscles of the region tends to produce the same results.

Acute Gonorrhea.—Purulent discharges from the urethra in typhoid fever, the secondary stage of syphilis, and as a result of irritation, are met with, but the usual cause of urethritis is undoubtedly the gonococcus of Neisser. The earliest symptoms, according to A. E. Garrow (*Montreal Med. Jour.*, March, 1900), are heat and itching in the glans, tickling and subsequent swelling at the meatus, increased tension in the penis, frequent micturition, ardor urinae, and a thin, greyish, watery discharge. Loss of appetite, general malaise, and a haggard appearance depend on the character of the nights. A seldom diagnosticated, but not uncommon complication, is spermatocystitis which is manifested by stabbing pain in the perineum, worse on urinating or defecting and radiating to anal and crural regions; rectal examination reveals a tender, nodular, sausage-shaped mass extending upward from the prostate and best outlined when the bladder is full. The treatment of this condition is to empty the seminal vesicles by pressure or massage, irrigate the posterior urethra and bladder, and treat otherwise as for acute prostatitis. For acute gonorrhea use hot irrigations of large quantities of bichloride or potassium permanganate solution, and follow by an injection of one-half to two per cent. protargol which is retained fifteen to thirty minutes. Irrigate twice daily during the first few days, then once a day. Internally, salol, ten grains three times a day, with cubebs, alkaline diuretics, anodynes and arterial sedatives. When the morning drop or gonor-

rheal threads persist, pencil with silver nitrate and apply 25 to 40 per cent. boroglyceride. For posterior acute urethritis order rest in bed, hot hip-baths and hot irrigations, have patient urinate with penis in hot water, and give injections of protargol once a day. Salol and Dover's powder relieve vesical tenesmus and an opium suppository or morphine may be required to secure rest at night.

After-Treatment of Peritoneal Section.—Henry T. Byford (*Am. Gyn. and Obstet. Jour.*, April, 1900) employs the following treatment after all cases of peritoneal section. The object of the treatment is to systematically induce peristaltic action as soon as possible after a peritoneal section for the purpose of preventing intestinal paralysis and adhesions. The treatment is begun by giving the patient four drams of fluid extract of cascara, or some equivalent, two hours before the operation. In those cases in which adhesions were separated and raw surfaces left, a high glycerin enema is given before the patient is taken from the table. In all cases dram doses of sulphate of magnesia are given every hour from the time the patient awakes after the operation, and a high glycerin and water enema—two to four ounces—every two hours, beginning eight hours after. This treatment must not be discontinued until the patient passes flatus not only with the enemas but also freely between enemas. In order to maintain frequent peristalsis and a daily evacuation of the bowels after the first days, the writer gives two drams of sulphate of magnesia or two or three ounces of Hunyadi water every night and morning for two weeks, regulating the size of the doses according to their effect. The treatment is sometimes modified, if the patient needs a stimulant, by adding an ounce of whiskey to the enema given on the operating-table; if much blood has been lost, a high beef tea enema is given instead and is repeated every four hours. Strong beef tea enemata usually cause vigorous peristalsis within twenty-four hours. Instead of the sulphate of magnesia small doses of Hunyadi water or liquid citrate of magnesia, or of the granular citrate may be given. Instead of the cascara, the writer often gives syrup of figs and when the glycerin does not act well, ox-gall enemata are substituted. As the result of this treatment Byford finds that there are practically no temperature cases, no crying for morphine, no bloating, no fixed pains, and seldom any subsequent pain in the ovarian region even when adherent appendages have been removed. The convalescence is more rapid and the patient more comfortable during it. In the simpler cases of peritoneal section treated in this manner the patient can, without harm, if the abdominal wound is entirely healed and well supported, get out of bed in ten or twelve days.

Spastic Esophageal Closure in Urinary Intoxication.—In cases of intoxication by means of retained urine, it often happens that disorders of the digestive system arise resulting therefrom. These disorders are usually the accompaniment of the chronic form of retention. S. Grosglik of Warsaw reports an interesting case in point. (*Centralbl. f. d. Krankh. d. Harn und Sexual-Org.*, B. xi. Heft. 2), in which specialists on internal diseases had made incorrect diagnoses of carcinoma of the stomach or intestine—such diagnoses depending upon the extreme emaciation and cachexia present. All kinds of internal medication consistent with the incorrect diagnosis were tried, but uniformly without success in such cases. The symptoms most striking are esophageal disorders, vomiting and diarrhea, and the combination of all three very soon conduce to the patient's extreme decline and emaciation. But the most important factor in this cachexia is the difficulty in swallowing solid food—the most distressing of all symptoms for the patient. French literature aptly terms this general condition as "*grande dyspepsie urinaire.*" The cause of this difficulty in swallowing is the marked dryness of the buccal cavity due to diminished glandular activity, hence the term "*dysphagie buccale.*" In his own case, Grosglik found the localization to be in the lower segment of the esophagus, which had led others to make the diagnosis of esophageal carcinoma. The condition was one that followed poor catheterization of the bladder, the symptoms of stenosis coming on very quickly thereafter. This rapidity of onset, determined Grosglik, could hardly have been due to carcinoma; and the combination of symptoms, seemingly uremic, suggested to him the possibility of a urinary cachexia rather than a carcinomatous one. Daily irrigations of the bladder with nitrate of silver, 1-2000, together with tentative feeding of fluids by mouth and rectal alimentation brought the patient around within two weeks. At the end of that time not only fluids, but soft diet could easily be administered per os and the patient began to nourish himself. The septic condition of the urine also constantly diminished until within twenty days the patient was discharged cured. The case proved interesting from the fact that it was the first one in which a spastic stenosis of the esophagus had been seen depending upon urinary intoxication. Internal medication is absolutely nugatory in such cases. The fact that the spasm lasted for so long a time and disappeared synchronously with the clearing of the urine proves that it was not a spontaneous closure, but one dependent upon urinary infection.

Meteorism in Typhoid.—W. E. Tschernow, (*Klin. therap. Woch.*, April 22, 1900) has obtained gratifying results from the local use of ice in combating tympanites in typhoid. The abnormal distention being due to excessive gas-formation and to paresis of the neuromotor apparatus of the intestine, owing to the infiltration of its walls with the product of abnormal fermentation, it follows that in case of diarrhea intestinal antiseptics would also be indicated. The author has found these drugs of good service,

and, contrary to recent experimental evidence, thinks they are well able to interfere with excessive putrefaction. In case of tympanites with constipation in typhoid, he recommends enemata of turpentine or asafetida, and advises direct puncture of the gut when the meteorism is so marked as to interfere with heart and lungs.

Secondary Suture of Brachial Plexus.—W. Thorburn (*Brit. Med. Jour.*, May 5, 1900) publishes a unique case of suture of the brachial plexus seven and one-half months after its traumatic rupture. There was complete paralysis and anesthesia of the limb with marked trophic changes. There was sufficient evidence to show that the nerves were not torn from the cord. At the time of operation the cicatrix between the ruptured ends was excised, and the various nerve-trunks sutured as nearly as possible in their old relations. After six and one-half months, without special treatment, the various functions began to reappear and have improved moderately up to the present time, four years after operation. This proves that the plexus is capable of repair after complete resection. The case would have shown more improvement with systematic massage and attention. This is the first reported case of suture so long after the primary injury. Its comparative success holds out hope for many limbs which would otherwise be condemned to amputation as useless encumbrances. In cases in which the nerves are torn from the cord operation is hopeless.

Ethyl Chloride as an Anesthetic.—To the general rule that no anesthetic is absolutely safe, ethyl chloride makes no exception, according to G. Lotheisen (*Münch. med. Woch.*, May 1, 1900). Opisthotonos, great excitation, cyanosis and asphyxia have followed its use. On the whole, however, the author's results were satisfying, in that the mortality did not exceed that of chloroform and, he thinks, with greater experience can be still further reduced. The stage of anesthesia is rapidly reached, recovery is prompt and kidneys, heart or lungs do not seem to suffer. In case of alcoholics it is good to precede the inhalations with an injection of heroin. During protracted operations, vomiting occasionally occurs, but is never so severe as with ether or chloroform. Narcosis should invariably be begun with small amounts and as soon as the slightest degree of cyanosis or excitement appears, the inhaler should be removed and the face vigorously rubbed with a cold towel.

Vasectomy.—R. Harrison (*Lancet*, May 5, 1900) says that vasectomy usually causes shrinkage of the prostate, except when carcinomatous, adenomatous or fibroid changes exist. The operation itself is slight and does no harm even in those cases in which little good seems to result. After following a number of cases for some time, he was able to demonstrate that the usual effect of vasectomy is shrinkage of the prostate; that although this shrinkage affords readier access to the bladder, it does not necessarily restore natural micturition, this failure being due to structural bladder changes resulting from the long-continued obstruction; these changes consist of varying grades of sacculation and trabeculation permanently damaging the vesical expulsive power. It is a most interesting fact that a comparatively small sacculation can throw the whole expulsive mechanism out of gear. Therefore, when vasectomy fails to give the desired relief one must look to structural bladder changes and, since these are the result of prolonged obstruction, the natural indication would be to shrink the prostate soon after the onset of obstructive symptoms. The best results of vasectomy have been obtained in cases on the border-line of the development of these structural changes, which continued catheterization does not remove. Vasectomy does not destroy sexual power as does castration; it is most useful in the earlier stages of prostatic hypertrophy; it is not useful in cases of fibroid degeneration or malignant change; it renders catheterism easier where changes in the bladder render normal micturition impossible even after prostatic shrinkage.

The Therapeutic Value of Iodipin.—All the preparations of iodine heretofore in use have the disadvantage of causing the train of symptoms known collectively as "iodism" before the particular drug administered has had the chance to be therapeutically effective. The cause of these symptoms may be ascribed to the rapid separation of free iodine from its compounds, notably the potassium iodide, and to its attacking the mucous membranes of the stomach and intestinal tract. J. W. Frieser (*Wiener klin. Rundschau*, April 22, 1900) describes his experience with a new iodine preparation, originally used by H. Winternitz and called "iodipin," which has none of the above mentioned disagreeable effects. This drug is manufactured by E. Merk in Darmstadt. In Frieser's practice, the result of its use was always a good one; it could be depended upon; it was better borne by the patient and decidedly more acceptable to him than potassium iodide; iodism or gastric disturbances could never be shown as a concomitant. When the patients objected to take iodipin on account of its oily taste, it was given subcutaneously or per rectum. Especially in lues was the result of iodipin noteworthy, in many cases being better even than the mercurials. These good results obtained by the use of iodipin are to be accredited to the fact of its slow decomposition within the body, the iodine being given off in all probability in the blood itself and that only gradually. This insures the gastro-intestinal tract against the malign influences of the free iodine and for that reason iodipin may be administered for a prolonged time without bad constitutional effect. The fact that iodipin circulates in the body-fluids and thereby becomes deposited in the various organs allows the freed iodine to act directly upon the cell and effect its economy. Frieser demonstrated the presence of iodine in

urine and saliva fifteen minutes after its administration per os, while after subcutaneous use it required three and four days to be detected in the same secretions. In the feces iodine was scarcely ever present. Iodipin, which is prepared from iodine and oil of sesame is to be obtained in ten and twenty-five per cent. strength. Its composition is based upon the well-known fact of the affinity of the halogens for fats. In appearance and taste it resembles oil of sesame. It is extremely stable, even months elapsing before decomposition sets in. The dose internally is two to three drams of the ten-per-cent. preparation, while per rectum as much as five to seven ounces may be given in clysms. The twenty-five-per-cent. iodipin is used exclusively for subcutaneous injection. The drug is to be given about two weeks at a time and its oily taste may best be disguised with ol. menthæ, syrup. cort. aurant. or other aromatics. For subcutaneous injection, about ten cubic centimeters are used in the gluteal region or the back. A needle of slightly larger caliber than usual is advantageous for this purpose. In order that the twenty-five-per-cent. iodipin may become less dense it is frequently warmed before using it by placing the bottle containing it in warm water. Besides using iodipin in syphilitic cases, the author has had much success with it in emphysema and asthma. Bearing in mind all the advantages of iodipin over potassium and other iodides, we are forced to consider the advent of this new preparation with the greatest favor.

Typhoid Infection without Intestinal Lesions. W. Ophüls (*N. Y. Med. Jour.*, May 12, 1900) reports another case of typhoid fever giving a positive Widal reaction in which no intestinal lesions were found at autopsy. The clinical symptoms were typical and unmistakable, the patient dying eight days after admission to the hospital in San Francisco. Thirteen cases have previously been reported, and these have been considered as proving that there are forms of typhoid infection with unusual primary localization of the virus. The author, however, believes that in his own case, as well as in several others reported previously, the organisms really came from the intestines and that the absence of anatomical lesions does not disprove this opinion. He reviews the cases showing that in many instances death came late in the disease, often as a result of a complication, and ample time had elapsed for complete recovery from any intestinal lesion. In his own case swelling and hyperplasia of the lymphatic mesentery-glands especially point to this fact.

Treatment of Hay-Fever by Suprarenal Gland.—The most constant clinical lesion of hay-fever is a nasal vasomotor paralysis with an accompanying congestion and edema, producing characteristic symptoms which are, however, never more than those of an acute inflammation of the respiratory mucous membrane. The accompanying local lesion and psychological factor which are supposed to complete the chain may be wanting. B. Douglas (*N. Y. Med. Jour.*, May 12, 1900) points out the peculiar antagonism which the action of suprarenal gland bears to the clinical symptoms of hay-fever and reviews the limited literature upon the subject. After considerable experience with the drug, he believes that no other remedy has such prompt and decided action. It may be given either internally or locally with the same result and has the enormous advantage over the ordinary remedies in leaving no after-effect. When used for a long time, both locally and internally, it may cause such a constant diminution in the nutrition of the parts that atrophy may result. Its best result is achieved in the simple cases in which the principal symptoms are those of a nasal and pharyngeal inflammation. The asthmatic tendency may be diminished, but where the asthma has already developed the drug seems to have very little effect. A combination of internal and local treatment seems to be best. A solution of six or twelve per cent. is made by shaking up the saccharated dried extract with water and decanting after one hour. This may be applied by spray every two hours till the symptoms are controlled. Internally, five-grain tablets may be administered every two hours at first, day and night, until giddiness or palpitation is observed or until the vasomotor paralysis is controlled. The dose may then be given at gradually increasing intervals. The author believes the drug to be almost a specific, but recommends the use also of other recognized adjuvants, such as digitalis, quinine, cocaine, and Clark's solution.

Premature Babies.—The clinical picture of these is characteristic, says J. D. Voorhees (*Archives of Pediatrics*, May, 1900). The head is large in proportion, the abdomen prominent, the face thin and peaked, the body jaundiced, covered with lanugo, the skin soft and delicate, wrinkled in some places or so thin that the veins shine through. The movements are very weak, the respirations irregular and superficial, and often suspended for a time. For treatment the essentials are to maintain a proper temperature, to give the proper amount and kind of nourishment, to avoid infection, and to prevent exhaustion. Without harsh methods of resuscitation, but by hot baths or light titillation, the baby is made to cry lustily, the cord tied off, its body anointed with albolene, and it is dressed, not with cotton which makes it perspire, but with a light shirt, and a napkin which is pinned over the feet and legs. It is then, without being bathed, placed in an incubator at 86° to 92° F., or kept in a properly-warmed room. Six hours after birth half to one teaspoonful of warm five- to six-per-cent. sugar-of-milk solution is given and repeated each hour. After twenty-four to thirty-six hours an equal part of breast-milk is added, not, however, from the mother's breast, but from a wet-nurse seven or eight days postpartum. The amount is increased one dram at a time until at the end of a

week the child it taking six or eight drams each hour. If the stools are normal, increase the breast-milk and diminish the sugar solution. The food may have to be given with a dropper, but generally the child will suck a small nipple. Occasionally gavage is necessary. After a week or two the child may be tried at the mother's breast two or three times a day, and, if it does well, every two hours. These babies are liable to cyanosis and require slapping or the administration of oxygen during the attack, and a few drops of brandy in hot water every two or three hours. Always first ascertain, however, that nothing has been aspirated into the larynx. The weak lungs and gastro-enteric tract make these babies especially susceptible to infections, and to the irritation of dirt in nose, mouth, eyes, and on the skin. The babies require to have napkins changed about four times a day. They gain weight slowly, and are doing unusually well if they reach their birth-weight at the end of two or three weeks.

Postdiphtheritic Laryngeal Stenosis.—J. Rogers, Jr., (*Annals of Surgery,* May, 1900) says that for years the treatment of laryngeal stenosis following diphtheria has been most difficult and unsatisfactory. Various operative procedures have been resorted to in vain. These operations were done under the belief that the stenosis was due to exuberant granulations, or to a contracting cicatrix following ulceration. As a matter of fact, the stenosis is due to subglottic hypertrophic laryngitis, which sufficiently explains the failure of the ordinary operative procedures. The author has cured several long-standing cases by inserting as large a tube as the larynx will admit without being lacerated and leaving it in place for from two to three months, removing it perhaps once for cleansing purposes. The tube must be of hard rubber, as the metal tubes become incrusted and cause ulceration.

Pleurisy Complicating Appendicitis.—From the consideration of a number of cases, M. Dieulafoy (*Bull. de l'Acad. de Méd.,* April 16, 1900) draws the following conclusions: There is an appendicular pleurisy as there is an appendicular liver, the former, however, being propagated by adhesions and lymphatics, the latter by the portal circulation. The pleurisy is found especially in recurrent appendicitis and usually occurs a few days after the onset of the abdominal symptoms, when the latter have begun to subside. The infection passes up behind the cecum and colon, its passage being marked by pus, adhesions, and at times encysted collections; the infectious products may penetrate the liver, or form a subphrenic abscess. They reach the pleura by perforating the diaphragm or by means of the lymphatics. Appendicular pleurisy is almost always right-sided, and may be confused with hepatic or subdiaphragmatic abscess. There are sharp pains in the right hypochondriac region and thorax, radiating toward the shoulder, a dry cough and intense dyspnea. Sometimes it is a dry pleurisy, sometimes an ordinary pleurisy with effusion, the infection being reduced to a minimum; but in most cases it is an empyema with a turbid, fetid and putrid collection. Auscultation and percussion give signs of great effusion, with sometimes evidence of pneumothorax due to the disengagement of gas by putrefactive bacteria. The prognosis is serious, depending upon the general condition, the state of the pulse, and the degree of enfeeblement. A fetid and putrid right pleurisy should always lead to an inquiry about appendicular signs in the preceding week or two. Surgical intervention should be prompt, and it may be necessary to operate for the appendicitis as well as for the empyema. The proper treatment is, however, prophylactic, and to this end the appendix should be removed in all cases of appendicitis, so that the numberless dangers and complications of this affection may be prevented.

Enteroptosis.—The cases of enteroptosis, writes Hector Maillart (*Revue méd. de la Suisse Romande,* April 20, 1900), may be divided into two groups, *viz.:* The hereditary, appearing in youth and producing permanent invalidism or rebellious neurasthenia, with persistently recurring stomach derangements, constipation, and headache; and the acquired, evidently due to purely mechanical conditions, usually beginning later in life and easily diagnosticated. Every physician knows that phthisis and cardiac disease are unfavorably influenced by pregnancy, but it is not well known that pregnancy may produce a temporary, and even a permanent, cure of enteroptosis. The enlarging uterus increases the intra-abdominal tension, and at the same time pushes back into place the organs which have fallen by gravity. The digestive functions improve, the neurotic condition disappears, and the patients gain flesh and vigor. After childbirth, when up and about, a binder should be applied over the lower part of the abdomen, and it should be made broader than below so as to support the abdomen without compressing it. The wearing of corsets must be avoided, and the weight of skirts should be borne by the shoulders.

Treatment of Muscular Rheumatism.—In alleviating the sufferings of both acute and chronic muscular rheumatism the physician is often handicapped by want of proper appliances to carry out the more extensive hydrotherapeutic measures, while, on the other hand, internal medication too often fails to allow him to dispense with the former. In injections of sodium iodate, S. Otto (*Therap. Monatshft.,* April, 1900) has found a simple procedure well able to replace the more elaborate ones. A single injection of 7.5 to 15 grains is usually followed by prompt relief. The drug should be introduced at the site of pain in the form of a five-per-cent. solution. Great care should be taken to have both salt and solution as fresh as possible, since the presence of free iodine causes much irritation.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

THE STAMPING-OUT OF SCIENTIFIC ADVANCE IN PSYCHIATRY.

THE progress of scientific research in psychiatry seems to be extremely diverse and tortuous. No sooner is an institution organized and making progress in the line of psychiatric research than a heavy iron hand is put on its very heartstrings with the intent to crush out its activity and life. Far be it from us to accuse the psychiatric profession as a whole of this terrible, if not criminal, work of oppression and suppression of scientific progress. No profession is as eager as the psychiatric to welcome scientific enquiry, but those who interfere with or arrest psychiatric research are not sufficiently stigmatized and branded by their psychiatric brethren. Whether this mercy to those who deliberately crush science is due to the lack of strength of collective professional opinion, or to the lenient spirit acquired by long experience in an atmosphere of intellectual bizarreness and moral aberration, it is certainly hard to tell. One thing is sure that such a state of things is extremely unfortunate and greatly to be regretted. Still more is it to be regretted when attacks in scientific research are committed by a man who, if he is not, still claims to be the chief and leader of the psychiatric profession in the United States.

As an illustration may be taken the present condition of the Pathological Institute of the New York State Hospitals. The psychiatric profession has put its hopes on the Pathological Institute, and not without reason. In this country and abroad the work of the Institute is hailed with delight. Important guiding principles for the work were laid out by the Director; methods for psychiatry were being elaborated by its staff of scientists and work of high scientific merit were being conducted and being depicted in the Archives; the Institute as a whole was fairly under way, when suddenly the Commission in Lunacy, of which Dr. Peter Wise is the President, bethought itself of the expediency of arresting the scientific work of the Institute, claiming its work to be "improper" and, to abet and assist in this destructive work, calling upon a committee of men that are unfit to judge of the scientific work of the Institute. Two of the committee are asylum-men, while the third is a pathologist who has no reputation as a psychiatrist or as a neuropathologist. This committee openly repudiates scientific work in psychiatry carried on by the Pathological Institute, thus attempting to arrest the progress of psychiatric science, and degrading it to a condition occupied a quarter of a century ago. We hope that the psychiatric profession, and particularly the American Medico-Psychological Association guarding its interests, will be aroused to indignation over the outrage committed on a scientific psychiatric institute by a committee of men who could not or would not regard the vital importance of research work in the science of psychiatry.

THE TENEMENT-HOUSE COMMISSION AND ITS WORK.

THE problem before the admirable Tenement-House Commission, whose appointment and personnel we referred to last week, is a serious and important one. As Governor Roosevelt well said, "It is second in vital interest to no other, not even that of the City Charter." By one of the ironies of fate, the Queen City of the newest of the great nations contains some of the most crowded areas that are to be found in the civilized world. The figures are simply appalling. According to *Charities*, the official organ of the Charity Organization, not a few single blocks, in the city, house and shelter a seething popula-

tion of fully 2000 inhabitants, and one of them, between Sixty-first and Sixty-second Streets and Tenth Avenue, reaches the deadly climax of 3978 persons. Even at the former rate this would work out a population of over 400,000 per square mile, and Mr. William Potts declares that certain areas in the city actually now contain over 1000 persons per acre—nearly double the density to be found anywhere else in the world. As this leaves barely forty square feet of service for each individual, little more than the historic six feet of English soil promised the Danish invader by the last of the Saxon kings, it needs no exercise of the imagination to conceive how not merely health, but the plainest decency, must be literally suffocated out of existence under such fearful pressure. Nor can we console ourselves with the thought that this condition is largely a heritage of the past, with its lack of legal control and its inability to conceive of the enormous rapidity of the city's growth, for, while Five Points has been wiped out and Mulberry Bend reformed, some of the worst instances of congestion are to be found in comparatively new regions of the city and in modern tenements. Indeed, many of the workers in the cause of tenement-reform declare the new sky-scraper, in spite of its imposing appearance, worse from a hygienic standpoint than the old barracks. Every room, it is true, is supposed to have its window, but when these windows open upon an air-shaft, two and a half feet wide and sixty feet in depth, their value as a source of either light or air can well be imagined. The air-shafts are far more effective as disseminators of foul smells and as huge flues, up which in case of fire the flames travel with incredible speed to every floor, than as ventilators.

Then, again, while every foot of space even in the darkest inside rooms of the old barracks was occupied they were only three or at least four stories high, and the actual number of people which they could pile upon a given ground area was less than that accommodated by the huge, high, modern building. It has come not to be a question of cubic space in bed-rooms and living-rooms, but of ground breathing-space and elbow-room, for in many of these neighborhoods the street is the only play-ground, and when six layers of budding humanity come to be discharged into them every morning, the situation becomes a serious one from this point of view alone. And as these tall insanitary types of buildings, relying upon the delusive air-shafts as a source of light and air, are being built at the rate of two thousand a year, it is high time that action of some sort be taken and the Commission has been appointed none too soon.

Although rapid transit has accomplished much in scattering the crowded thousands of workers over wider areas, the shape and surroundings of Manhattan Island are so unfortunate, from this point of view, and the population is increasing so rapidly that little permanent relief can be hoped for from this source, especially in the lower districts, and the battle must be fought out in the tenements themselves.

No member of our profession needs to be reminded of the relation of overcrowding and disease. Years ago the authorities of Berlin began collecting facts with tireless Teutonic patience and were able to show that nearly half the death-rate of the city occurred in families living in single rooms, although they constituted about one-eighteenth of the entire population. Their mortality-rate reached the astonishing pitch of 163.5 per 1000 per annum, more than eight times the normal city rate. Among families living in two rooms the rate fell to 22.5 per 1000 and to as low a figure as 7.5 in families occupying three or more rooms.

At the late International Congress upon Tuberculosis in Berlin, carefully-prepared studies showed that England headed the roll of honor among the nations and London among the cities with the lowest death-rate from tuberculosis. This was attributed chiefly to the small number of inhabitants per room and per house as compared with the Continental nations and cities, so that the connection between this disease and overcrowding is a close and constant one, as the experience of Naples has also shown. In all the over-crowded blocks alluded to in our opening paragraph the death-rate exceeds the city average in New York by from 10 to 18 per 1000 or from 50 to 85 per cent. Probably few more vivid and impressive demonstrations of this connection have been made than the disease chart of the admirable tenement-house exhibit held at Sherry's old rooms last February. In this the tenements were represented by pink color-blocks, the length of which indicated the proportion of the ground-space occupied, while the incidence of the four chief infectious diseases, tuberculosis, typhoid, scarlet fever and diphtheria, was indicated by variously-colored dots. The blocks and the dots grouped themselves together in the most striking manner. Wherever tenements were more than

three stories high and occupied more than fifty per cent. of light- and air-space, there the dots clustered thickly and, contrary to general impression, as we have already stated, many of the old three-story barrack-areas showed less of both disease and poverty than the modern five and six-story buildings. In one block in Cherry Street fourteen out of the twenty-two houses showed the black dot indicating tuberculosis, and in one of these, No. 144, known to fame as the "Ink-Pot," were no less than seventeen cases of the disease.

The task before the Commission is no light one for the forces which make for the maintenance of the present state of affairs are enormously strong. Chief among these, of course, are the necessities of the tenant and the greed of the speculative builder and landlord. One wonders that the working classes submit to such fearful herding together but, as two-thirds of the population of New York City are compelled to live in tenements of some class, the best that is offered them is a choice of evils. Indeed, the stern necessities of the situation in some cases drive them to actively assist in the overcrowding. The average rent-rate in New York is no less than 24 per cent. of the tenant's earnings, as compared with 12 per cent. in Berlin, and to meet this drain families not only crowd into a disastrously small room-space but take in boarders as well. Especially is this the custom in the Italian tenements, where two or more families will sometimes occupy a single room which is simply packed with bunks and cots. And when these crowded rooms open not upon the street but upon air-shafts, fourteen inches wide and twenty-five feet deep, with thirty-nine windows opening into it, the condition of the atmosphere can be better imagined than described. Yet in these dark dens, worse than the original cave-dwellings of the race, the rents range from ten to seventeen dollars per month for from three to four rooms, the price of an entire house in most suburbs. And such houses as these are actually being erected under the present law, which Commissioner Brady of the Building Department declares to be "all that it need be," and the Tenement Commission, consequently, a complete superfluity.

This dictum, however, will not greatly discourage the newly-appointed body which has practically decided that the facts in the case are already so well known through the work of the Charity Organization Society and of other investigators, including many of the members of the Commission itself, that they can proceed at once to the consideration of what can be done to remedy the situation by legal measures. The outlook before them, although stormy, is far from discouraging, for the experience of Glasgow, London, Birmingham, and Berlin, has already shown what immense improvements can already be hoped for from judicious regulation seconded by persistent individual effort. How this success has been attained we hope to discuss in a future issue.

ECHOES AND NEWS.

NEW YORK.

New Cure for Diphtheria.—We learn from Santiago de Cuba that leading members of the medical profession report radical cures of diphtheritic cases by the initial application of paraffin.

Emergency Hospitals in Brooklyn.—Charity Commissioner Simis proposes to take a large number of dwelling-houses, scattered in various parts of the borough, and use them as emergency hospitals. They will each accommodate from twenty to thirty patients.

The Harlem Hospital.—Commissioner Keller in a recent address declared that the most glaring need in the Department of Charities is a new hospital in Harlem. The present Harlem Hospital, he said, is a makeshift from top to bottom, a disgrace to the city, and a reproach to the intelligence of the people of New York. The Commissioner also announces his intention of converting the building occupied by the Cornell Medical School in the Bellevue Hospital grounds into a first-class, up-to-date maternity hospital. The Maternity Hospital on Twenty-sixth Street will be occupied as a dormitory for the Bellevue Hospital employees. In the autumn three buildings on Blackwell's Island will be appropriated to the use of segregating tuberculosis patients.

Contagious Diseases.—For the week ending May 12, 1900: Measles, 559 cases and 14 deaths; diphtheria, 288 cases and 44 deaths; laryngeal diphtheria (croup), 9 cases and 7 deaths; scarlet fever, 166 cases and 12 deaths; chicken-pox, 11 cases; tuberculosis, 241 cases and 197 deaths; typhoid fever, 21 cases and 13 deaths; cerebro-spinal meningitis, 1 death. Totals, 1295 cases and 288 deaths.

Medical Societies Merged.—At a special meeting of the New York Medical Association, held May 11th, in the New York Academy of Medicine, it was unanimously voted that the County Association should become merged into the New York State Medical Association under its new charter recently obtained at Albany. The action taken was a ratification of the proceedings of the State Association in making all county organizations subordinate associations.

Walter Duryea Able to Write.—Walter Duryea, who sustained a fracture of a cervical vertebra in August last while diving and who was operated on a month later by Dr. Abbe in Roosevelt Hospital, where he has been a private patient ever since, is now able to write. On May 11th he amused himself and delighted his friends and attendants by showing that he had sufficient strength and control of his movements to write his name and several short sentences.

New York State Board of Health.—Dr. Daniel Lewis of this city was reelected President of the State Board of Health at the annual meeting of that body held at Albany, May 11th. Dr. S. Case Jones of Rochester and Dr. Frederick W. Smith of Syracuse were appointed a commission on tuberculosis, and Drs. Lewis, Jenkins and Smelzer were appointed a committee to investigate the best system of disposal plants.

St. John's Guild.—This charity, which cares for thousands of poor and sick children during the summer months, has received two valuable gifts. Mrs. Augustus D. Julliard, whose husband in 1899 presented the Guild with a new floating-hospital, the "Helen G. Julliard," has given to the Guild the sum of $50,000, the interest on which is to be used to defray the expenses of operating the boat. Another gift is that of Mrs. Frederic Elliott Lewis, who has arranged for the erection of a new cottage-hospital on the grounds at New Dorp. This gift is in memory of her son, Frederic Chandler Lewis. The cottage is to be detached from the other buildings of the group, and is for the care and treatment of infants who are very ill. During 1899 the Guild gave 82,824 days of treatment at a cost of $57,993.12. The Guild needs $60,000 for the work this year, as it has largely increased its field of labor.

The March Death-Rate.—There were 7522 deaths in New York City during March; this gives a death-rate of 24.3 per thousand population. The death-rate in Manhattan Borough that month was 24.4; The Bronx, 33.4; Brooklyn, 23.0; Queens, 21.4; and Richmond, 26.4. One-ninth of these deaths were caused by consumption. The State Board of Health has decided to include pulmonary tuberculosis in the list of infectious and contagious diseases, to be thus reported monthly by the health officers of the different municipalities of the State. The State Board expressly declares that in requiring cases of consumption to be reported it by no means desires to have consumptives isolated or to institute a system of inspection. The Board's intention is to secure, if possible, a census of the number of cases actually existing in the State. Such a census being necessary to determine as to the necessity for State care of consumptives and for making some estimate as to the seriousness of the question from a sanitary point of view.

Dedication of Medical Library Building.—The dedication of the new library building of the Medical Society of the County of Kings occurs on Saturday, May 19, 1900. The new building is an attractive and imposing structure, a cut of which appeared in the MEDICAL NEWS last year. The exercises include addresses by Dr. George M. Gould of Philadelphia, Dr. James R. Chadwick of Boston, and Dr. Abraham Jacobi of New York; also appropriate remarks in transferring and accepting the building by Dr. William Maddren, Chairman of the Building Committee, Dr. Frank E. West, Chairman of the Board of Trustees, and Dr. Lewis S. Pilcher, President of the Society.

PHILADELPHIA.

Warned Against the Plague.—The secretary of the State Board of Health has issued a circular warning the public against the bubonic plague and advising vigilant observance of sanitary laws as a preventive. Especial attention is called to the mining villages of the State, their filthy condition rendering them particularly liable to outbreaks.

Health Report.—Deaths for the week ending May 12th were 494, a decrease of 23 from those of the previous week and an increase of 90 over those of the corresponding week of last year. Contagious diseases: Scarlet fever, 70 cases, 6 deaths; diphtheria, 90 cases, 18 deaths; typhoid fever, 60 cases, 15 deaths. Influenza was responsible for 5 deaths, and 2 new cases of cerebrospinal fever were reported.

Associated Health Authorities and Sanitarians of Pennsylvania.—The seventh annual meeting of this Association will be held at Mechanicsburg May 23-25. Discussion on school hygiene will be opened by Miss Dora Keen of this city. Dr. A. C. Abbott, City Bacteriologist, will deliver an address.

Woman's Medical College.—The forty-eighth annual commencement of this College was held May 16th, a class of twenty-four being graduated. A portrait of Dr. Ann Preston, the first woman who held the position of dean of the College, was presented by the alumnæ. An address by the Chinese Minister was a feature of the day. A full report of this and of the Alumnæ meetings of May 17th and 18th will appear in a future issue of the MEDICAL NEWS.

Pathological Society.—At the stated meeting of May 10th Drs. Shumway and Posey reported a case of sarcoma of the choroid. The points of interest in the case were: The advanced age of the patient, seventy years; the unusual form of the growth, which was of the alveolar type and originated from the proliferation of the lining endothelium of the larger vessels of the choroid; the early appearance of glaucomatous symptoms; marked inflammatory changes in the iris and ciliary body; the probable metastasis to the liver and brain. This was indicated by the sudden death of the patient a short time after enucleation of the eyeball, although no autopsy was obtained. Dr. Simon Flexner exhibited a tumor which had caused death in a patient by blocking

the small intestine just above the ileocecal valve. The tumor was ulcerated and was supposed to be a cancer although no microscopical examination had been made. No macroscopic evidence of metastasis was present.

Jefferson Commencement.—The seventy-fifth annual commencement of Jefferson Medical College was held on Tuesday, May 15th. The President of the Board of Trustees, Hon. Wm. Potter, conferred the degree of M.D. upon the 106 members of the class of 1900. James D. Moffat, D.D., LL.D., President of Washington and Jefferson College, delivered the address. The speaker began with a history of Jefferson College in Canonsburg, under the charter of which the Jefferson Medical College was founded. He does not commend the tendency of young men to enter the profession earlier in life, but argues for maturer years and a more thorough preliminary education.

County Medical Society.—The regular meeting of May 9th was devoted to a discussion on malaria. Dr. W. S. Thayer, of Johns Hopkins University, read a paper upon "The Life History of the Malarial Parasite." The three methods of transmission of the parasite—by the air, by drinking water, and by the bites of insects—were considered, with the conclusion that evidence points strongly to the last. Some facts were given as to the distribution of the Anopheles, the species of mosquito which has been proved to transmit the disease. In the city of Baltimore, where malaria is not found, the Anopheles is not present; but in the suburbs where malaria is present the insect is easily obtained. In a town of North Carolina, which white people had practically left because of malaria, 50 specimens of the Anopheles were obtained in two hours while the Culex was not found. Upon going eight miles into the interior of the country from this town, the Culex was found but the Anopheles was not. This region was also free from malaria. The speaker concluded from these facts, which have been noted in various countries, that, whether or not all cases of malaria can be accounted for by bites of insects, there is no positive evidence in favor of any other method of transmission. Nearly all the cases of spring malaria are considered to be relapses. The most interesting work now to be followed is to determine the type of mosquito present in given localities, the breeding-place of the same, and the best methods of extermination. Very much aid to investigators can be given by country physicians reporting the time of beginning of epidemics, the relation of these to relapses, the relation of the presence of the disease to the different types of mosquitoes, etc. Dr. Alfred Stengel spoke on "The Diagnosis of Malaria." The quartan type is very rare in Philadelphia. He has examined the blood from cases which have been pronounced malarial neuralgia, malarial disease of the eye, malarial lethargy, etc., and has never found the malarial parasite in any of them. In regard to the statement that the diagnosis of malaria should never be made unless the parasite be found, he believes that the experienced clinician may sometimes do so. The fact that the organism may be present in the internal organs in large numbers and not in the peripheral circulation does not warrant the microscopist in being too absolute in his conclusions. Puncture of the spleen will probably serve to make the diagnosis certain when the parasite is absent from the peripheral circulation. This method has certain risks, however, and is never necessary in the local types of the disease.

County Medical Society.—The meeting of April 25th was devoted to a discussion of medical education and the recent rulings of the Medical Council of Pennsylvania. Dr. Henry Beates, Jr., of the State Board, gave the reasons for the Medical Council insisting upon four years devoted to the exclusive study of medicine as a requirement for candidates for the State license. Dr. W. W. Keen maintained that college graduates should be given credit for their work and admitted to advanced standing in medical schools. The Medical Council is composed of seven members, none of whom are teachers, only three are physicians, and three of the other four are not educators in any sense, the fourth being the Superintendent of Public Instruction. Hence, it is a mistake to have these men supervise the medical education of the commonwealth. In many colleges the graduates are better fitted for the second year of the medical school than are those who take the first year of the medical school without a college course. If four full years are required of college graduates one of three results will follow: (1) Young men will eschew a college course and begin medicine; (2) they will pursue from one to three years at college and then begin medicine; (3) graduates will go to medical schools of other States where they are recognized. Dr. H. C. Wood believes the first year of a medical course should be taken at a medical school instead of at a lay college. It is better to dwarf the college than the medical course. A high college education is not the best thing for a medical man in all instances. President Stahr of Franklin and Marshall College stated that if college graduates were obliged to enter the first year of a medical school instead of to advanced standing with men of their own caliber they would go to other States. If medical schools demand the degree of A.B. for entrance, then literary colleges will acquiesce. President Warfield of Lafayette stated that with the physicians in their faculty and the facilities for dissection which they possess, they can turn out a better product than can medical schools with their first-year work. President Birdsall of Swarthmore stated that their graduates would pass all the examinations of the first year in the medical schools. Dr. S. Weir Mitchell asked if he meant to include anatomy and was answered that it included everything. The medical schools could build their fences and

the college boys would climb over them. Dr. Edmund Holmes, Demonstrator of Anatomy at the University of Pennsylvania, said that college graduates knew more anatomy than did the men who had taken the first year in the medical school. This is due to the fact that the men in small classes at the colleges possess opportunities which he and his small corps of assistants are not able to give at the medical school. The Society passed resolutions demanding that college graduates be given credit by medical schools for the studies of the course which they have already taken.

CHICAGO.

Why Operate and When in Appendicitis.—Dr. J. B. Murphy spoke upon this subject at the April 25th meeting of the Chicago Medical Society. In speaking from a mortality standpoint, he excluded three classes of cases and retained only one. He excluded appendicular colic. He believes there is such a thing, but does not regard it as a surgical lesion. A diagnosis of appendicular colic can be made. He excluded catarrhal appendicitis as it is generally understood, saying it does not materially, if ever, jeopardize life. He excluded partially recurrent appendicitis, not the acute infective variety of the disease, but the mild so-called recurrent form, which may be either a recurrent catarrhal appendicitis, or a recurrent appendicular colic. In the consideration of the subject he included largely the acute infective form of the disease. Surgeons operate to remove an organ which is acutely infected, and in a very large proportion of cases during the first twenty-four hours, this infection is confined to the wall of the appendix. Indeed, he ventures to say that in ninety-nine cases out of a hundred, in the first twenty-four hours, the disease is limited to the wall of the organ. He omits one per cent., because he has in over nine hundred cases seen four cases of primary perforation from fecal concretions, and he is willing to admit that a few more cases than that may have occurred which had advanced beyond the possibility of recognizing that condition at the time operation was undertaken. Let the pathologic process advance to the second twenty-four hours and the condition will vary from an increased quantity of pus or inflammatory débris in the appendix to a completely gangrenous or necrotic appendix, or to perforation of the organ, with a circumscribed or general peritonitis at the end of forty-eight hours. There are cases of appendicitis dying daily. Why are they dying? Not because they are not within the reach of competent surgical treatment. He has noticed that a large percentage of them die in large cities and among popular, very influential people. Why? First, because this important class of people are treated conservatively, and by conservatively he means cowardly, because the medical man is either incompetent of making a diagnosis, which is positive, on which he is willing to risk his reputation; or, secondly, cowardly because the surgeon is not ready to face the music and take the responsibility of the risk. Surgeons can operate during that time, that is, the first twenty-four hours, with a mortality of two per cent. at the maximum, as he has never seen a death from a case operated upon inside of this period. The mortality in patients that are operated upon on the second, third, fourth, or fifth days is very much more than two per cent. Does the danger of operation increase with time? Yes, very materially, because the pathologic conditions have changed in the abdomen. For what purpose do surgeons operate? To lessen invalidism; to lessen or prevent recurrent attacks.

When should surgeons operate? If the danger increases with time; if the mortality increases with time; if the convalescence increases with the length of time which elapses between the onset of the attack and the time of operation, there is no ground for postponing operation, if it is indicated, beyond the first twenty-four hours. Taking all of the cases, one with another, in fairly competent hands a mortality of two per cent. can be obtained by operative intervention, and the only time it is possible for a surgeon to have this low mortality is inside of the first forty-eight hours. Inside of the first twenty-four hours the chances are much better; the surgeon is much more certain of his ground. Shall the surgeon operate when the case has gone to the third or fourth day? That depends. If the case has advanced to the third or fourth day and there is a circumscribed appendical abscess, with low temperature, the indications are that the virulence of the intoxication is not great. Then the surgeon can with safety wait. Even then, however, the risk is greater in waiting than in operating at that particular time.

GENERAL.

American Therapeutic Society.—The following officers have been elected: President, Horatio C. Wood, of Philadelphia; 1st vice-president, Howard H. Barker, of Washington; 2d vice-president, R. W. Wilcox, of New York; 3d vice-president, E. H. Long, of Buffalo; secretary, Noble P. Barnes, of Washington; recorder, William M. Sprigg, of Washington; treasurer, John S. McLain, of Washington.

The Pure-Food Bill.—The House Committee has submitted a favorable report on the measure now before Congress designed to prevent the adulteration, misbranding, and imitation of beverages, foods, candies, drugs, and condiments, and to regulate interstate commerce in such commodities. The bill, as now worded, creates a chemical bureau in the Agricultural Department whose duty it shall be to inspect food and drug products. It is sincerely to be hoped that this measure may become a law.

The Huxley Memorial Statue.—On April 30th a statue of Huxley was unveiled by H. R. H. the Prince of Wales in the great hall of the Natural

History Museum, South Kensington. The director of the Museum explained that this statue was the expression of admiration not only of the English people, but of the whole civilized world for one who, as discoverer, writer and man, must be reckoned among the greatest figures in the records of our age. Subscriptions have poured in, amounting in all to over $16,000, from all parts of the world, including every state of Europe, India, the United States, and England's remotest colonies.

The Plague.—There continue to be reports of plague at Hong Kong. In India reports still confirm the increased virulence and steady advance of the epidemic. In Honolulu all quarantine restrictions were abolished on April 30th, the city being pronounced absolutely free and clean from all infection. The plague is reported as spreading along the Red Sea, several cases have appeared at Port Said, and the American Consul General at Cairo cabled to the Secretary of State, May 9th, that the plague had appeared in Alexandria.

The Increase of Smallpox.—According to the latest "Public Health Reports" of the United States Marine Hospital Service, there were 7648 cases and 402 deaths from smallpox in this country during the first three and a half months of the present year, and 5267 cases and 272 deaths during the corresponding period of 1899. This is an increase this year of 44 per cent. in the number of smallpox cases and 48 per cent. in the number of deaths from that disease.

Beriberi Among the Japanese.—Kakké or beriberi has until recently been the most prevalent malady in the Japanese fleet, at times absolutely paralyzing action, just as formerly European squadrons used to be afflicted with scurvy. In 1882, during the Corean expedition, and about the same date, in a fleet off the coast of South America, beriberi rendered helpless between 30 and 40 per cent. of the total strength.

The Mosquito and Filaria Nocturna.—Dr Manson has succeeded in demonstrating the filaria in the blood, stomach, and other sections of the mosquito. In one microscopic section, passing through the entire length of the proboscis of a filariated mosquito, a specimen of this parasite was seen stretching along the entire length of the proboscis. It was inferred that the filaria is communicated to man by the bite of the mosquito. "This important discovery," says the *British Medical Journal*, "not only revolutionizes our ideas as to the precise way in which the mosquito conveys the filaria to man, but by analogy lends support to the truth of Ross' inoculation theory of malaria."

Some Medical Problems in the Philippines.—In an article in the *Atlanta Medical Journal* with the above title Dr. Bourns states that the Filipinos and the Spaniards at Manila know practically nothing about hygiene. But the Filipino is willing and quick to learn and will adopt whatever is good and beneficial when convinced. Smallpox is always there. The native is a fatalist, and will not take any pains to avoid this disease, believing that if he is to die of it, it is so ordered. But while vaccination is resisted at first, when its utility is appreciated, the Filipinos will offer themselves voluntarily for vaccination. Leprosy is quite prevalent. There are about 2500 lepers in the islands.

Hygiene Exhibit for Paris.—An interesting exhibit for the Paris Exposition is that of public hygiene, which was shipped on May 5th. In the absence of a National department of health, Dr. Samuel W. Abbott, Secretary of the Massachusetts Board, special agent for the United States Commissioner, prepared the exhibit. All the States are represented, except a few in the West where there are only local health boards. The collection will be a part of the exhibit of social economy and public charities and hygiene. The following is a general enumeration of the articles comprised: Half-a-dozen large maps of the United States, illustrating subjects relating to the public health; a series of cards in wing frames, showing the vital statistics of the country as a whole, and of States and cities; maps and charts indicating the work of several State boards of health, of isolation hospitals for infectious diseases, of hospitals and homes for consumptives, of vaccine and antitoxin plants, and of crematories; six folios of circulars of State and local boards of health, and a large album full of photographs elucidating municipal healthwork; reports of the various health boards, of registers of marriages, births, and deaths, of dairy and food commissioners, and of sanitary organizations, and periodicals of the same class; a glass case containing appliances employed here to facilitate the diagnosis of infectious diseases, together with samples of antitoxines and vaccine lymph.

Yale Medical School.—The Yale Medical School is to be enlarged and to be removed from its present site in New Haven to Cedar Street, Congress Avenue and Rose Street in that city. The frontage of 400 feet is to be on Cedar Street, opposite the State Hospital. The land has cost from $50,000 to $75,000. The change will probably be made slowly, owing to the lack of funds. However, a new dispensary will in the near future stand on the proposed grounds. This change in the medical department is of a general scheme to develop, as far as possible, all branches of the University, illustrated some time ago by the university's purchase of the ground on which the new Law School building stands. The Yale Medical School is one of the oldest in the country.

OBITUARY.

Landon Carter Gray, A.M., M.D.

Dr. Landon Carter Gray, whose death was briefly noted in our last issue, afforded in the record of his life a notable example of how much, in results and in honors attained, can be accomplished within the brief compass of a few short years. Born in New York City April 3, 1850, he had barely passed his fiftieth birthday on May 8th, the date of his death. To those to whom the heritage of good birth is significant in its bearing upon the individual, it is interesting to note that Dr. Gray counted on both sides a long line of honorable and distinguished ancestors. His father, a lawyer of prominence and ability, was directly descended from "King" Carter of Shirly and Westover, two of the most famous Colonial estates of tidewater Virginia. His mother, a Miss Ireland, of the well-known New York family of that name, was a descendant of the Swedish Consul Jans, progenitor of the famous Anneke Jans heirs. Dr. Gray's boyhood days were passed at his father's home on Staten Island where he received his early education, afterward matriculating at Columbia College. He had scarcely completed his junior year, however, when he was compelled to abandon his studies on account of progressively failing vision, which had followed an attack of scarlet fever. This defect of vision was, by the way, of such pronounced character and degree as to render one eye practically useless through life, a statement which will doubtless surprise many who knew him intimately. The same illness appreciably affected his hearing, which defect also remained through life and was often a source of great personal annoyance to him. Upon leaving Columbia he went to Europe and, his eyesight improving, he entered the University of Heidelberg where he remained as a student for three years. Returning to New York he began the study of medicine, graduating from Bellevue Medical College in 1873. He was immediately offered, and accepted, the position of assisant to Dr. James R. Wood with whom he remained, however, only a year or two, finding no special aptitude nor inclination for surgery. He began practice in this city on Park avenue near 40th street. Within a year or two he moved to Brooklyn where he almost immediately began the special study of neurology. It was during these early years in Brooklyn that he passed through the fiery trial of financial adversity. Reared in an atmosphere of affluence and luxury he was the less prepared for the change which his father's total loss of fortune made necessary. In connection with this incident of his life it would be less than just to the memory of the man and to the dominant characteristic of his private life not to mention the fact that without legal obligation and with none other than that of the nicest honor, he voluntarily assumed and afterward paid, out of his own personal earnings, thirty thousand dollars in settlement of the indebtedness incidental to his father's failure. The spur of necessity proved an additional stimulus to an already active ambition with the result that in less than ten years he had not only reached the top-most round in the city of his labors, but had won for himself a name and reputation reaching international proportions. At the age of thirty-two he was filling with distinction the Chair of Neurology in the Long Island Hospital College of Medicine. A few years later he resigned to accept the professorship of Mental and Nervous Diseases at the New York Polyclinic, a school for post-graduate instruction of which he was one of the founders. He returned to New York in 1886 where he continued actively at work until within two or three months of his death, persisting in a determination to continue "in harness" in spite of a constant distress of mind and body incidental to the disease which caused his death, which disease (a chronic nephritis with cardiac complications) was existent and known to him for several years.

His energy and worth were not unrewarded. Honors fell full upon him. His titles were many, only a few of which need be mentioned. He was Visiting Neurologist to St. Mary's Hospital in Brooklyn, Consulting Neurologist to the Hospital for the Ruptured and Crippled, President of the American Neurological Association, of the New York Neurological Society, of the Neurological Section of the Academy of Medicine, of the Society of Medical Jurisprudence and of the New York County Medical Society; Honorary Member of the Medical Society of the District of Columbia, besides many others. For nine years he held the position of chairman of the Executive Committee of the Congress of American Physicians and Surgeons, a most distinguished honor.

Dr. Gray was the author of many valuable contributions to neurology and psychiatry. He discovered and demonstrated the value of surface variations in the temperature of the scalp as a means of diagnosis in certain intracranial affections. He discovered and described a symtomatic entity among the convulsive disorders akin to chorea to which he gave the name palmus. Especially noteworthy and valuable were his original observations and published teachings upon syphilis of the nervous system, melancholia and the muscular atrophies. The crowning accomplishment, however, of his literary career is a treatise on mental and nervous diseases which has passed through several editions and ranks as a most valuable and authoritative text-book on the subject.

In no sphere of professional activity, however, did Dr. Gray attain to more deserved distinction than in that of the medico-legal expert. His opinions and advice were in constant demand, and he commanded a respect and confidence which cannot be better illustrated than by a tribute by one of New York's ablest jurists, a judge for many years of one of our highest courts, pub-

lished in the *New York Sun* of the 14th inst.: "Dr. Landon Carter Gray had also achieved notable distinction in the field of legal medicine. In giving expert evidence he was the very model of what a medical witness ought to be, and his intellectual honesty would not suffer him to be biased in favor of the litigant or lawyer who sought his opinion. This was so well known that distinguished counsel often consulted him in regard to medical matters which never found their way into court, simply in order to satisfy themselves as to the true character and extent of the injuries or maladies of which their clients complained."

Passing from the public to the personal man the task becomes more difficult. Dr. Gray was a many-sided man, and like all great men he had his angles. Of handsome physique, impressive presence and somewhat imperious manner, an acquaintance short of intimacy left often an impression less than just. To those who knew him no underestimate was possible. Of unswerving truthfulness, keen to exquisite nicety in his appreciation of the right, kindly and generous in every instinct, he was a type of the loyal friend and the generous foe. To him as to others of like type the cardinal crime was ingratitude and to repay an obligation with interest was with him instinctive. He was an intellectual pugilist and was never oblivious to the gauntlet thrown down before him. The atmosphere of the intellectual arena was as sweet incense and to this measuring of wits he went as to a feast. He never acknowledged defeat and yet he bore no malice from disaster accomplished by fair means. He was bold to audacity. To the writer he once said: "I always take the odd chance. In all my life I have never walked nor crawled, I have plunged." His sense of humor was always keen, his stories always apt. As an after-dinner speaker he was often in demand. As a teacher he was peculiarly coherent and practical. He possessed in extraordinary degree the quality of adaptability, which faculty made him preeminent as an instructor. He was a most voracious reader and, therefore, a "full man." His three years' residence abroad, coupled perhaps with natural aptitude, made him an accomplished linguist. One special quality he possessed in most phenomenal degree—a quality which has made the military chiefs of history—the faculty for organization. Of a child-like type of credulity apparently, he was accurate in his estimate of men and kept constantly attached to him by obligations of interest and gratitude men who not only served his purposes but justified his estimates in personal successes which cast a reflected glory, which was his. In this he suggested the elder Charcot. Of those who, in his special field, stand highest in New York to-day, not one but owes some tribute to his memory, the younger men for his determined efforts to check them in their fascinating but unfounded theories, and to the more mature for his loyal support in their well-considered theories.

CORRESPONDENCE.

OUR LONDON LETTER.

[From Our Special Correspondent.]

LONDON, May 10, 1900.

THE MIDWIVES' BILL—DINNER TO SIR WILLIAM MAC CORMAC AND MR. FREDERICK TREVES ON THEIR RETURN FROM SOUTH AFRICA—EFFICIENCY OF THE ARMY MEDICAL SERVICE—LARGE BRITISH LOSSES AND COMPARATIVELY SMALL BOER LOSSES IN ENGAGEMENTS—THE "PLAGUE OF WOMEN" IN SOUTH AFRICA—THE "HOME OF GENIUS"—DESCENT FROM ANCIENT CIVILIZED RACES IN THE PRODUCTION OF GENIUS—HEREDITY.

THE Midwives' Bill still remains the burning question of medical politics, so far as any question can be termed burning in a phlegmatic race and in a profession incapable of uniting and taking an active part in any public matter. This bill, which has passed its second reading in the House of Commons by a large majority, has been brought forward in order to regulate the practice of midwives. According to its provisions no woman will be allowed to use the title of midwife, or to hold herself out as practising as such, who has not been legally registered. In future to obtain registration a woman must undergo a prescribed course of training and pass an examination. She will be empowered to attend only normal labor; if complications arise a medical practitioner must be summoned. The majority of the rank and file of the profession appears to be hostile to the bill. They say it creates a new order of medical practitioner who necessarily will be imperfectly trained and that therefore their recognition will be fraught with disasters to puerperal woman. They insist that these midwives cannot in their limited course of training learn to diagnosis normal from abnormal labor. In a poll of the profession taken by the *Lancet* only 1311 out of 6299 practitioners expressed themselves in favor of the Bill. However, it must be remembered that of the whole profession in England and Wales not a third took the trouble to vote, so that the opinion of the silent majority is still in doubt. On the other hand, the opinion of the higher classes of the profession, so far as it has been expressed, is strongly in favor of such legislation. It has been recommended by the Obstetrical Society, the General Medical Council, and the Council of the British Medical Association. The leading medical journals maintain a very guarded attitude, which may be described as one of veiled hostility. The only one which has made an outspoken declaration in favor of the Bill is the *Practitioner*. It has the courage of its convictions and boldly declares that the opposition is conducted in a spirit of sordid selfishness and that in all the noise made by the leaders, but one argument can be detected, the *argumentum ad crumenem*. It must be confessed that this is largely true. The interests of the public have not even been considered by these gentlemen except

to furnish them with a fallacious argument. The question is not one of well-trained accoucheurs *versus* ill-trained midwives but of untrained *versus* trained midwives. From 50 to 75 per cent. of labors in this country are attended by midwives—in most cases because the fee of a medical man cannot be afforded. Puerperal fever is often spread by these ignorant and untrained midwives. With official training and supervision this could easily be prevented. As to alleged danger from the incapacity of midwives to recognize serious complications, the answer is: Trained midwives are much more competent to do so than untrained ones.

Sir William MacCormac and Mr. Frederick Treves have been entertained at a banquet by their fellow members of the Reform Club on their return from the South African War. Lord Rosebery presided and the Lord Chief Justice and many well-known politicians attended. The chairman proposed the health of the guests in a characteristic speech. He referred to the services of Sir William MacCormac in the Franco-German War which first brought him into prominence and to the sacrifice of these two distinguished surgeons who, without a second thought, at the call of the government, left their great practices to superintend the surgical arrangements of the army. In a war in which there was so much diversity of opinion, absolute and enthusiastic unanimity existed on one point and on one point only—that the medical service was perfect. In his reply Sir William MacCormac said that at the battle of Colenso in consequence of the adverse conditions under which the British forces fought, their losses amounted to 1140, while those of the Boers were 5 killed and 25 wounded. He knew this on good authority. The latter occupied an almost impregnable position which was shelled for two days. For every 1000 shells the Boer losses were only 12 killed and 40 wounded. Such was the result of modern improved guns! The injuries from rifle-bullets were mild and less destructive than he had ever seen before. Injuries from artillery were comparatively few. Mr. Treves said that there never had been a campaign in which the horrors of war were so mitigated by surgical aid. There were two plagues in South Africa—flies and women. The latter were an absolute terror. Having exhausted every form of excitement they came out in the guise of amateur nurses and were to be seen at Cape Town and other places gaily dressed and giving picnics. Considering the war in which the country was engaged this was a blot on the campaign.

In the current number of his *Archives of Surgery* Mr. Jonathan Hutchinson puts forward a very ingenious and fascinating hypothesis on the subject of genius. It is not, perhaps, generally known that in addition to his encyclopedic knowledge of the whole field of medicine, he possesses a minute acquaintance with biology in general and with the allied or subsidiary sciences of geology, anthropology, and history. The hypothesis to which I have referred is a characteristic product of his subtle intellect; it is at once a daring and original hypothesis and a carefully made deduction. One of his patients has a head remarkably like that of Shakespeare. He at once asked him whether he was of Warwickshire family. The patient was, his ancestors having lived for many generations in Warwick, and he was of strongly pronounced literary tastes and abilities. Mr. Hutchinson had previously written a paper on the remarkable production of genius in the vicinity of Shakespeare's birthplace. Within a radius of fifteen miles of Coventry were born Shakespeare, George Fox, Butler, the author of "Hudibras," George Eliot, and Walter Savage Landor. Mr. Hutchinson suggests that possibly in this district there is some surviving Roman strain, for, here, in the very center of England the Romanized Britons were less disturbed than elsewhere. Here, too, was a confluence of Roman roads. Probably what is called genius is seldom or never produced in races only recently civilized, but occurs in those who in some degree trace their descent to the older stocks. The features of many European men of genius suggest an admixture of Semitic blood, and during the 360 years of the Roman occupation many of that race must have left descendants.

Prof. Arthur Thomson's lecture on "Heredity" at the Royal Institution of Great Britain, was an able and lucid exposition of an exceedingly difficult subject. Three kinds of inheritance were distinguished: (1) *Blended,* in which the characters of the two parents in regard to a particular structure, *e. g.,* the color of the hair, is intimately combined in the offspring. This form is well seen in hybrids and is probably the most frequent mode of inheritance. (2) *Exclusive,* in which the character of one parent is suppressed in regard to a structure, *e. g.,* eye-color. (3) *Particulate,* in which part of a given character is wholly paternal and part wholly maternal. Suppose the parents of a foal to be light and dark. If the foal is piebald the inheritance is particulate. Inheritance is not dual but multiple. A man, says Mr. Pearson, "is the product of all his past ancestry, and unless very careful selection has taken place the mean of that ancestry is probably not far from that of the general population. In the tenth generation he has theoretically 1024 tenth great-grandparents. It is the heavy weight of this mediocre ancestry which causes the son of an exceptional father to regress toward the general population mean." The transmissibility of acquired characters was considered not to have been established, but if the effects of "nurture" could not be entailed on the offspring, it was all the more important to secure for them good "nurture."

Death Penalty in Massachusetts.—By the narrow margin of two votes the House to-day decided against abolishing the death penalty in Massachusetts, the roll call recording 86 against and 84 in favor.

CYSTS OF THE BREAST—DIAGNOSIS AND TREATMENT OF CHRONIC NASAL DISCHARGES—INCARCERATION OF A GRAVID UTERUS NECESSITATING ABDOMINAL SECTION AND CYSTOTOMY—CASE SIMULATING PERFORATED GASTRIC ULCER.

At a meeting of the Medical Society of London, April 23d, T. Bryant spoke of cysts of the breast, to which he has given especial attention during the past four years. From personal observation he has been able to collect 242 consecutive cases of breast-disease. Excluding 12 of these in which the diagnosis was not confirmed by operation, there remain 163 cases of malignant trouble and 67 of cystic disease. Bryant draws the following conclusions: That simple cysts of the breast are far more common than they are generally thought to be; that they are chiefly found in women at the same period of life as that in which cancer is met with; that they are mostly amenable to local treatment without the sacrifice of the breast-gland in which they are situated; and that there is no reason to believe that women who have these cysts are more prone to cancer than those who have them not.

At the Harveian Society of London, April 5th, Edmund Roughton introduced a discussion on the diagnosis and treatment of chronic nasal discharges. He limited his remarks to the treatment of the accessory nasal sinuses. In antral empyema the essentials of treatment are: (*a*) The removal of the cause; (*b*) the evacuation and drainage of pus; (*c*) antiseptic irrigation; and (*d*) the removal of morbid material when present. Thus it would be futile to irrigate the antrum through the nose while it was constantly reinfected by carious teeth. Drainage alone will not suffice for a cure if the walls are polypoid, but it is wrong to scrape out an antrum which is simply a pus-receiver from a frontal sinus. In most cases treatment should be begun by antral drainage with a fair-sized tube. When this does not succeed the radical operation can be resorted to, an opening being made through the canine fossa. The treatment of frontal empyema is divided into intranasal and extranasal. The former comprises removal of the anterior part of the middle turbinate and irrigation of the cavity through the infundibulum. If these methods fail extranasal treatment may be resorted to, for instance, if there is persistent pain or evidence of imperfect drainage. Ethmoidal suppuration should be treated by the removal of the middle turbinate and scraping of the affected cells, care being taken not to transgress the anatomical limits of the lateral mass of the ethmoid. Any direct operative attack on the sphenoid should be undertaken only after the most careful consideration.

Herbert Tilley said that the pain of chronic suppuration is due to accumulation of pus under pressure and not to inflammation of the nerves in the walls of the sinuses. In support of this opinion cases were cited in which the pain had instantly disappeared as soon as free drainage had been secured by the removal of a tooth, irrigation of the antrum from the nose, or the removal of the anterior half of the mid-turbinal, and of obstructing polypi and granulations from the region of the mid-meatus. In testing for pus in the antrum by transillumination, the patient's comparison of the subjective sensation of light in the eyes is sometimes of more value than the surgeon's comparison of the facial illumination. Tilley believes in antral drainage as a preliminary measure in all cases of antral suppuration. It is a simple method of treatment and often cures the patient. It can usually be carried out without the removal of a sound tooth.

At the Obstetrical Society of London, April 4th, J. M. Kerr reported three cases of incarceration of a gravid uterus. In one of them the operator found it necessary to open the abdomen and then the bladder, and was unable to replace the uterus until he had removed a large quantity of blood-clot from the bladder. The bladder and abdomen were then closed. The patient recovered and continued to full term.

A. H. N. Lewers criticised this method of treatment, saying that he had seen many cases in which the retention of urine was extreme, over five pints having been drawn off, and in two of the cases there was hematuria, but the performance of abdominal section was not suggested. His treatment was to empty the bladder and to replace the uterus, preferably under anesthesia, or to encourage the uterus to rise spontaneously by rest in bed and regular evacuation of the bladder. Such spontaneous reposition is not unusual. In the case mentioned by Kerr the urethra might have been dilated and the clots removed by forceps and irrigation, and if the bladder had only been kept empty for a few days with the patient constantly in bed, he suggested that the uterus would have spontaneously assumed a correct position.

At the Royal Academy of Medicine in Ireland, March 9th, W. J. Thompson read notes on a case simulating a perforated gastric ulcer. The patient was a female, aged twenty-three years, who had a tubercular family history but who had never been seriously ill except for a period of six weeks. She suffered from mild digestive disturbances, flatulence and nausea. Later there was pain, localized at first in the pit of the stomach and afterward extending to the back. About an hour after a simple supper of bread and milk, the pain suddenly became agonizing and was followed by vomiting; the vomited material being, according to report, of dark reddish color. The pain increased during the night and became more diffuse. The epigastric and left hypochondriac regions were tense and tender. Liver dulness was present. Fourteen hours after the acute attack the abnormal symptoms were aggravated,

the pulse 140, respiration 34, temperature 102° F. A median incision was made and the anterior wall of the stomach examined. It appeared normal. The operator was about to examine its posterior wall when he discovered a coil of jejunum containing two gangrenous patches involving one-third of the bowel. The loop was resected and the ends joined by a Murphy button. The patient recovered. The specimen was lost and the cause of the gangrene was not determined, but the case is of interest as showing how difficult is an infallible diagnosis of acute abdominal lesions. The previous history, the sudden nature of the attack, and the localization of pain all pointed to perforation of a gastric ulcer.

SOCIETY PROCEEDINGS

AMERICAN SURGICAL ASSOCIATION.

Twenty-first Annual Meeting Held at Washington, D. C., May 1, 2, and 3, 1900.

THIRD DAY—MAY 3D.

(Continued from Page 714.)

Surgery of the Stomach.—The discussion was opened by Dr. W. W. Keen of Philadelphia, who said that the subject naturally divided itself in benign troubles and malignant troubles, and of these two classes the latter is the more difficult and more important. It is practically in the first three months that the surgeon must operate on carcinoma of the stomach if he expects to be successful. The advent of gastric specialists is a great help to the surgeon, but in every case in which there is a suspicion of cancer, if medical measures fail to relieve, an exploratory operation should be made without delay.

Dr. M. H. Richardson of Boston said that in stomach diseases, all methods of diagnosis should be exhausted before exploratory incision is performed. Explorations of the abdomen are dangerous. When other means of diagnosis have been exhausted and a doubt remains, then an exploration should be made, and, just as in acute cases after traumatism and so forth, the exploration should be made without delay. The future of surgery of malignant disease of the stomach is more hopeful than is generally believed.

Dr. Thomas A. McGraw of Detroit called the attention of the members to a method of gastro-enterostomy by elastic ligature which was first performed by him upon a human being in 1891. The junction of the stomach and intestine was perfect. The patient died in fifteen days of inanition, and at autopsy the surgeon found that he had anastomosed the very lowest part of the ileum to the stomach. One advantage of this operation is that it is the safest form of gastro-enterostomy. The rubber ligature can be stretched and threaded through a darning-needle smaller than the ligature. Hence the opening made in the stomach and intestine will be smaller than the rubber thread which passes through them and no leakage can occur. The speaker said that he has performed this operation many times upon dogs with entire success. In the dog it takes four days for the portion of the stomach which is included in the ligature to slough away. In man the length of time required is probably three days.

Dr. Allen of Detroit mentioned a case of perforated ulcer of the stomach which was situated so far posteriorly that it was impossible to reach it. The patient was quickly put into Trendelenburg's posture, and the fluid and gas were removed from the stomach by a stomach-tube. The area of the perforation was stuffed with gauze, and the patient recovered. Culture media inoculated with the peritoneal fluid remained sterile.

Dr. Tiffany of Baltimore said that he had seen but one case of carcinoma of the stomach, and that at autopsy, in which the condition was such that an operation could be done with reasonable expectation of a radical cure. The speaker advocated an exploratory operation in order to make a diagnosis. He said that surgeons came to their present knowledge of ovarian troubles only by operating many times and often needlessly, as they have since learned; that the same is true of appendical difficulties; and that knowledge of gastric lesions and the best means to meet them must be acquired by the performance of many operations, wise and otherwise.

Dr. R. F. Weir of New York said that the surgeon is called upon to relieve one or more of the major symptoms of pain, hemorrhage, delay of food in the stomach or dilatation. When the abdomen is opened he must then decide as to what operation will best relieve the symptoms. Speaking of the technic of gastro-enterostomy he said he preferred the posterior method combined with entero-anastomosis of the ascending and descending legs of the intestinal loop. Since adopting this procedure he has never seen the vicious vomiting which formerly caused the death of some of his patients after gastro-enterostomy. He prefers a Murphy button not only because of the facility with which it can be employed, but also because its punched-out hole gives security against subsequent contraction which is not offered by even a long sutured slit.

Dr. Armstrong of Montreal said that he had operated on a number of cases of hemorrhage of the stomach. These cases are of two classes, one in which superficial vessels are opened and which are amenable to medical measures, and those in which a deep and large vessel is opened, and in which death quickly follows either the first large hemorrhage or a succeeding one. The stomach should be opened in the anterior wall so that its inner surface may be most satisfactorily explored. Then, if necessary, a pyloroplasty or other suitable operation may be done.

The Methods of Closing Abdominal Incision.—Dr. M. H. Richardson said that for various reasons he favored a through-and-through suture. It leaves no dead spaces to be filled with fluid, and

so give rise to sepsis. Hence, herniotomy sutures being in layers are especially liable to suppuration. Silkworm gut is preferable to silver wire since it has all the advantages of wire and can be more rapidly put into place. The buried silk suture is best for the ligation of arteries as well as for layer sutures. Hematomata of different parts of the body show a different predisposition to infection. Those of the breast and amputation stumps do not usually become infected, while in a hernia the blood-clot almost always does so. This difference is probably due not to the suture material, but to the dirty operative field. Every operative field has some micro-cocci in spite of all attempts to cleanse it, and this is particularly true of the region of a hernia. There are very few ventral hernias after aseptic operations. The through-and-through suture obliterates the dead spaces, especially between the peritoneum and the muscular layer. If a buried suture is wished the muscular layer should be sutured. Then with a through-and-through suture the whole wall is firmly closed.

Dr. Deaver of Philadelphia endorsed Dr. Richardson's views. He is sceptical in regard to the sterilization of catgut. Whenever it is possible to do so, incision should be made through a muscular portion of the abdominal wall.

Dr. R. F. Weir of New York said that the disadvantages spoken of as due to the layer suture might have other explanations; for example, tying a suture too tightly may cause death of tissue and so give rise to hernia. The men who perform abdominal operations very likely do not see patients who afterward, disappointed with the result of their operation, apply to another surgeon for relief of a ventral hernia.

Dr. G. R. Fowler of Brooklyn advocated a figure-of-eight suture so that the threads cross between the peritoneum and the muscular or fascial layer. He considers that a purse-string suture of the peritoneum is less likely to be followed by adhesions and hernia than is a linear continuous suture.

Dr. Coley of New York said that clinical evidence has demonstrated the aseptic qualities of properly-prepared catgut. He referred to the last 150 cases of hernia in which operation has been performed at the Hospital for Ruptured and Crippled in New York City only absorbable sutures being employed. In but a single instance was there suppuration of the wound, and cultures of the skin of this patient made at the time of operation, and cultures afterward made from the discharge of the wound both contained the same streptococcus while tests of the catgut showed it to be sterile.

Dr. Vancrede of Ann Arbor said that catgut can be made as sterile as anything else by boiling it in kumol at 160° to 170° C., as has been shown by repeated laboratory tests; while it has also been shown that the ends of a sterile catgut ligature contain the same germs as the bare hand of the man who ties the ligature.

Dr. Ransohoff of Cincinnati said that the continuous buried suture can be used rapidly and easily in layers. His plan is to put a buried suture in the peritoneum, and in the muscular layer a continuous suture, the ends of the latter being brought out and through the skin. He then closes the skin by an intracuticular suture. It is better for a patient to have a single linear scar than one with numerous crossbars.

Strangulated Hernia Through Rupture of the Diaphragm.—Dr. E. W. Walker of Cincinnati reported an instance of this rare condition, the result of an accident, which was successfully relieved by operation. The incision in the median line revealed, after some search, a knuckle of prolapsed bowel tightly pressed into a rent in the diaphragm. It was withdrawn and an attempt was made to suture the rent in the diaphragm, but owing to the labored respiration of the patient the attempt was abandoned and the abdomen was closed. Recovery was uneventful.

Hernia of the Bladder Through the Pelvic Floor.—Dr. Francis B. Harrington of Boston reported a case of fibroma with attachments extending from the left labium magus to the left buttock. The tumor arose from the subperitoneal tissues in front and to the left of the bladder. It had drawn the bladder out of the pelvic cavity through the fibers of the levator ani muscle. Nearly the entire bladder was enveloped by the tumor which hung between the patient's legs. The tumor was 18½ inches in circumference and 8½ inches long. When the bladder was emptied the tumor decreased 2½ inches in its circumference. The bladder held 22 ounces of urine without discomfort. The urine did not flow until a soft rubber catheter had been inserted 8 inches. The tumor was removed and the hernia of the bladder reduced by a combined abdominal and external operation. The broad ligaments were separated from the uterus and the fundus of the uterus was drawn forward and to the left and sutured in that position as a plug to prevent the recurrence of the hernia. The operation was entirely successful and when seen six months later there had been no recurrence of the hernia of the bladder. Hernia of the bladder through the pelvic outlet is a very rare condition. No case, according to Brunner having been recorded in medical literature since 1860.

Aneurism of the Renal Artery.—Dr. W. W. Keen of Philadelphia operated with success upon a tumor supposed by him to be a sarcoma of the right kidney. The tumor was so vascular that its pedicle had to be ligated in seven places to control the hemorrhage, but it was not until the tumor had been removed and cut into that it was seen to be an aneurism. Aneurism of the renal artery is one of the rarest forms of aneurism, only twelve other cases having been reported. The cause in six cases, including that reported by Dr. Keen, seems to have been an injury. In most cases no disease of the general arterial system seems to have been present. Pain is not a prominent symptom. The tumor is usually smooth and elastic and, if it follows an injury,

it grows less rapidly than does a hematoma, but more rapidly than a sarcoma. The sac is very large and the artery relatively small and, hence, pulsation has not been noted in more than one instance. Without pulsation, naturally, a thrill would not be present, although in only one instance is it mentioned that the surgeon auscultated the tumor. One of the most important symptoms is hematuria. If the aneurism is situated outside of the kidney this will not take place until the aneurism attains considerable size and bursts into the pelvis of the kidney. In one case it developed within the kidney and there was hemorrhage from the first. Only three patients have been operated upon, and they all recovered. There was nothing peculiar about any of the operations, other than the danger of hemorrhage from the pedicle.

Acute Tuberculosis of the Mesenteric Glands.—Dr. M. H. Richardson of Boston said that he had come to look upon this disease as hopeless, unless the glands could be removed by operation just as is done in tuberculosis of the neck. The miliary form of peritoneal tuberculosis is not accompanied by enlargement of the mesenteric glands. When they are distinctly enlarged, ascites is generally absent. The mesenteric glands may be found enlarged, in cases of chronic appendicitis or under other conditions. They may be caseated or even calcified. In acute appendicitis the nearest glands may be distinctly affected. It is by no means unlikely that the original trouble is an acute tuberculous affection of the appendix, which may not be recognized as such until a persistent sinus or the progress of the disease in the glands reveals the true nature of the lesion. In the case reported diagnosis of acute appendicitis was made, but the appendix was found to be normal. Several enlarged and inflamed glands were removed from the mesentery, most of them were juicy, two contained cheesy degenerated areas. The operation was performed five years ago and the boy is still in excellent health.

Congenital Cystic Tumor of the Pelvis.—Dr. De Forest Willard of Philadelphia reported the occurrence of the above-mentioned trouble in a neurotic man. On account of the pain which extended down his leg, his physicians had made a diagnosis of neuritis; but the pain did not follow the course of any nerve, and was not continuous. Afterward a tumor was found in the groin and was operated on. It was of a cystic character and was so intimately connected with the iliac and femoral arteries that it was impossible to remove it *in toto*. Numerous bean-shaped yellowish bodies were taken from the cyst the nature of which was not clearly ascertained. The patient died later of nephritis.

Carcinoma.—Dr. L. Freeman of Denver mentioned two unusual phenomena in connection with carcinoma. A woman aged thirty-five years, from whom a carcinomatous breast had been removed, suffered spontaneous fracture of the femur while turning in bed. Apparatus was applied and, contrary to all expectation, the bone firmly united. After the death of the patient sections of the femur showed that the cancer had invaded the bone through its Haversian canals. In another patient an apparently typical cancer of the lip disappeared spontaneously. Later the submaxillary glands became enlarged and were removed. Microscopic examination showed them to be carcinomatous.

AMERICAN GYNECOLOGICAL SOCIETY.

Twenty-fifth Annual Meeting, Held at Washington, D. C., May 1, 2 and 3, 1900.

(Continued from Page 728.)

FIRST DAY—MAY 1ST (Cont.).

Conservative Surgery.—Dr. W. L. Burrage of Boston read a paper, entitled "The Remote Results of Conservative Operations on the Ovaries and Tubes, with Analyses of Eighty-five Cases." After referring to the results obtained by Drs. Polk and Dudley in this line of work, he gave a most thorough analysis of his cases and reached the following conclusions: (1) It is advisable to do conservative operations in all cases where the tubes are not hopelessly diseased in all parts of their stricture, except on patients who are near the menopause, on patients who have pronounced gonorrhea of long standing, and on the rare cases of malignant disease. (2) When a patient is near the menopause (over 35 years fo age) and has ovarian or tubal disease of any considerable degree of severity it is generally wiser to perform complete removal with or without hysterectomy according as the uterus is diseased or not. (3) In cases of well-marked gonorrhea of long standing, especially if the patient is constantly exposed to reinfection, if both tubes are seriously diseased and closed total removal, with or without hysterectomy, is the operation of choice. (4) In certain cases of this class where the patient thoroughly understands the likelihood that another operation may be necessary at some future date and wishes to take the chances in the hope of preserving the functions of menstruation, conservative operation is permissible. (5) If one tube is patent and healthy in appearance and there is enough healthy ovarian tissue to preserve, a conservative operation ought to be performed even in the presence of gonorrhea. (6) With present methods of performing resection of the tubes, if both tubes are found closed at the time of operation subsequent pregnancy is not to be expected. (7) In severe grades of inflammation of the appendages irrespective of causation if the ostium abdominate of one tube is patent the prospect of subsequent pregnancy after the preservation of a portion of the ovary is about one in four and a quarter or 23½ per cent. (8) In the lesser grades of inflammation under similar conditions of tube and ovary the prospect of subsequent pregnancy is about one in two and a quarter or 44 per cent. (9) In women who have borne children, in both classes, subsequent preg-

nancy may be expected in 35 per cent., whereas in the previously sterile it may be looked for in only 5 per cent. (10) If it is necessary to remove both ovaries, it is of no advantage to preserve any portion of tubal tissue, but, except under the conditions just enumerated, some ovarian tissue should be preserved in every case.

Dr. Thomas Addis Emmet of New York opened the discussion by saying that one should always be conservative for nature can do wonders at repair. It is of benefit to leave even the smallest possible bit of healthy ovarian tissue. This was well exampled by two cases in which he had pursued this course, and subsequently both patients became pregnant.

Dr. Dudley of New York said that he had now performed the conservative operation in 138 cases without a death. In one of these cases, which was a gonorrheal infection, there was a double pyosalpinx. He removed one ovary and split the other one and removed a V-shaped piece. He separated this from the tube and buried it in the fundus of the uterus. The ovary grafted and since then the patient menstruated normally. He had had 5 cases in which he has transplanted the ovary with marked success. Two of them are now menstruating; 1 has not yet had time to menstruate; 1 was never seen again, and 1 is not menstruating. The function of menstruation should always be conserved if possible and the patient thus spared the nervous shock.

Dr. Harris of Paterson, N. J., says that it is very rare to have to remove all or both ovaries. The only cases in which he does so are those which have large abscesses in the ovary. There are many advantages in leaving the ovaries from the standpoint of health as well as that of sentiment. It is believed that the future will show many cases of pregnancy as the result of such conservative treatment.

Dr. Vineberg of New York said that the class of cases which give the poorest results are those in which the lesion is not very severe; no matter what treatment is employed, the patients continue to suffer after operation.

Dr. Mann of Buffalo reported a case in which he had removed one tube and one ovary, the other tube and ovary being also infected. He did not remove them but merely incised them. Since then the woman has given birth to three girls and one boy, and is a splendid example of the good results to be obtained by conservatism.

Dr. Goffe of New York said he always believed in conservatism and was now approaching his one hundredth operation in which he had practised it. He prefers the vaginal route to the abdominal, and uses the actual cautery to burn out cysts in the ovary. In one case he removed two-thirds of the right ovary and applied the cautery six times to the left ovary. The woman is now pregnant.

Dr. Hunter Robb of Cleveland reported a case which had not been very successful. He performed a conservative operation at first, but in six months the patient had many distressing symptoms, so he made an abdominal incision and found that both ovaries were densely adherent and that the surface of the ovary had become converted into a blood-cyst. He removed both ovaries.

Dr. Burrage closed the discussion by saying that he had used the cautery on many cystic ovaries, but that he did not believe it had any advantage over simple puncture. He thought that every case should have a careful bacteriological examination made before operation, as the knowledge thus gained would be a guide as to the method of procedure, or, in other words, as to whether a radical operation was imperatively demanded, as would be the case in tubercle infection.

Internal Secretion of the Ovary.—This was the title of the paper read by Dr. Arthur W. Johnstone of Cincinnati. He said that there is absolutely no proof that the ovary has any other function than the manufacture of eggs. During all the life of the individual the Graafian follicles ripen. The ovary is in no sense a gland. Its epithelium is arranged for the purpose of being cast off and lost, and it is not placed so that its secretions, if it have any, could be absorbed either by ducts or blood-vessels. Delayed menstruation in a child-bearing woman produces identically the same symptoms as those of the menopause, which would certainly make the internal secretion of the ovary seem a myth. He does not believe the ovary dominates the health of woman, but rather that there is a center in the spinal cord which is the controlling factor. The good results following the administration of ovarian extract are generally seen in hysterical women who have also been known to improve on a mixture of salt and soda. Nature has its periods of rest and work, as seen in the moulting of birds, which corresponds to the menstruation of woman. It is simply a time of increased oxidation. Some women stand this period well, while others, particularly those with the gouty diathesis, do not. This is a very large source of trouble at the menopause and during menstrual life. In proof that the ovary's influence is not paramount, the author cited a case of a girl who had both ovaries removed on account of cysts at the age of 8 years. When seen twelve years later she had developed into a beautiful woman, her figure well rounded out, the possessor of a good voice, and an examination of her external genitals showed them to be perfectly normal.

Suturing the Round Ligaments.—Dr. H. N. Vineberg of New York read a paper on "The Technic, Indications and Ultimate Results of Suturing the Round Ligaments for Retroversion and Retroflexion of the Uterus." He describes his technic as follows: The patient is prepared as she would be for a vaginal hysterectomy. The nymphæ are sutured to the skin of the thighs so as to keep them out of the way. The cervix is then seized with two vulsella and forcibly drawn outside the vaginal orifice and downward, and

the anterior vaginal wall is caught with another vulsellum near the urethral meatus and drawn upward, thus putting the anterior vaginal wall on the stretch. With a sharp scalpel or one with a convex blade a longitudinal incision is made, extending from the urethral mound to the vaginal attachment of the cervix. The two flaps thus created are now separated partly by blunt and partly by sharp dissection from the underlying bladder. In order to give ample room generous separation of the vaginal flaps should be made. The lower angles of the flaps are then held apart and the cervicovesical septum is divided by a semilunar incision about 1 cm. below the lowest attachment of the bladder to the cervix. Before making this incision it is prudent to pass a sound into the bladder and ascertain how far down upon the cervix the bladder reaches by gently pushing the sound downward and forward. The bladder is next pushed up from the uterus with the index finger, as is done in vaginal hysterectomy. A short vaginal retractor is now inserted into the anterior opening, thus keeping the bladder out of the way and exposing the vesico-uterine fold of peritoneum. The fold is caught with forceps and a transverse incision made with scissors just below their bite. Before loosening the hold of the forceps a suture is carried through the peritoneum above the point of the incision, and it is left long and clamped. Its purpose is to draw down the bladder peritoneum towards the end of the operation when the slit made in the peritoneum is sutured. The cervix is now pushed backward into the posterior fornix with the vulsella, thus tilting the body of the uterus somewhat forward, and with the anterior vaginal retractor in place a traction suture is carried by means of a short, stout needle through the exposed anterior uterine wall as high up as possible. With this suture the uterus is further anteverted and brought into the incision. It may take one or more additional traction sutures, each carried higher up on the uterine wall, to completely deliver the fundus through the incision. With the index and middle fingers the adnexa, one after the other, are brought into the incision, subjected to visual inspection, and to such surgical treatment as their condition calls for. It is astonishing with what ease in the majority of cases a resection of an ovary or of a tube can be accomplished in this manner. The adnexa having been replaced within the peritoneal cavity, the uterus is retracted to one side, and with a small fine needle a silkwormgut suture is carried behind the round ligament of the opposite side about three or four cm. from its insertion into the uterus. Some care is necessary in passing this suture to avoid the small arterial branches which supply the ligament, as a troublesome hemorrhage may occur from the needle piercing one of them. A second suture is passed in the same way one or two cm. nearer the uterine insertion. The ends of the sutures are secured above and below with small artery clamps, which may be numbered so as to avoid confusion when it is necessary to carry the sutures through the vaginal flaps. This procedure is repeated on the opposite side and the uterus is returned within the peritoneal cavity by pushing the fundus backward with the fingers and drawing the cervix downward and forward with vulsella. The outer round ligament suture is now carried with a leading suture through the vaginal flap at a point corresponding to the anterior lateral sulcus and as near the pubic arch as possible. The inner suture is passed through the flap at a suitable distance inward from the first. The same thing is done on the opposite side and the sutures are tied loosely in the vagina while the uterus is being held forward by means of the traction sutures. The traction sutures are then cut and removed. The upper edge of the peritoneum is next drawn down by means of the suture which is attached to it, and the slit in the peritoneum is closed by a continuous catgut suture. In the event of a cystocele or a redundant anterior vaginal wall having been present, a strip of suitable width is excised from each vaginal flap, and the two flaps are coaptated by a continuous catgut suture. The last couple of stitches are made to catch up the cervical tissue so as to attach the vaginal wall to the cervix, as normally obtains. When the uterus is unusually large and heavy, or when the uterorectal ligaments are put on high tension by anteverting the uterus, it is wise according to my experience to employ a single uterine fixation suture in addition to the round ligament sutures. This suture should not be placed too high upon the uterine wall so as to avoid the possibility of dystocia in the event of pregnancy. Finally, any operation on the cervix that may be called for is now done, and the posterior vaginal wall or peritoneum subjected to any plastic operation that may be deemed necessary. The patient is kept in bed for twelve days, at the end of which time the round ligament sutures may be removed, as may also the uterine suture if present.

Dr. Cushing of Boston opened the discussion by saying that he does not think there is anything new in the first part of this operation. He considers it better to do it from above and should only do it in those cases where it desired to operate on the cervix at the same time. He prefers to operate through an abdominal incision as then he is able to see all the organs and can remedy all defects that are apparent.

Dr. Sutton of Pittsburg said that he had done this operation with uniformly good results. It is to be hoped that the time is not far distant when the majority of abdominal operations will be performed through the vagina. At present it is possible to remove large fibroids or ovarian cysts by this route.

Dr. Bovée of Washington said that he sees little use for shortening the round ligaments through the vagina as Alexander's operation is a better one, there being no opening of the peri-

toneal cavity. The greater number of cases of uterinal dislocation are due to injuries to the pelvic floor either as the result of childbirth or else through the faulty attachment of the fascia. The great point to be observed is to properly adjust the ligaments. If they are attached too high, lower them, or, if they be relaxed, take a reef in them. In other words, correct the deformity present in each particular case. When the fascia is torn high up the abdomen should be opened, the peritoneum dissected up, and the torn fragments brought together and sutured. Generally pelvic adhesions are present in all forms of dislocation of the uterus, so when performing Alexander's operation it is well to open the inguinal rings and explore the pelvic cavity before completing the operation. Constipation and infrequent urination are often the cause of failure after Alexander's operation.

Second Day—May 2d.

Vaginal Route.—Dr. J. Riddle Goffe of New York continued the discussion of Dr. Vineberg's paper and said that the era of doing all pelvic operations by the vaginal route has arrived. No laparotomy is justifiable until an attempt has been made to perform the operation through a vaginal incision. The work can be performed quite as successfully as it can through the abdomen. He has performed myomectomy, and operated on ectopic gestation, dermoid cysts, salpingitis, etc., with great success by the vaginal route. In his opinion the best operation for the cure of retroversion is by making the incision through the vagina, then double the round ligaments on themselves. It is a much better operation than Alexander's, as it is applicable to all forms of displacement whatever their complication. In one patient he removed seven fibroid tumors by myomectomy through the vagina and at the same sitting cured a long standing retroversion by shortening the round ligament.

Dr. Sutton of Pittsburg said that he preferred the vaginal route to the abdominal, as drainage was always very much better through the vaginal vault than through the abdominal walls. Dr. Vineberg closed the discussion by saying that he had taken up the vaginal route because ventrosuspension by the abdominal method had not given good results in his hands. Each case should be considered very carefully for a certain proportion will require operation by the abdominal route.

A Comparison of Vaginal and Abdominal Operations, by Dr. G. Richelot of Paris, France, was then read by title and will appear in full in a subsequent issue of the Medical News.

Demonstrations of Casts Illustrating the Anatomy of Pregnancy and Labor.—These were shown by Dr. J. Clarence Webster of Chicago. The casts were made of plaster of Paris and had been modeled after frozen sections. They were an interesting demonstration of the good results which may be accomplished in this line of work.

Combined Nephrectomy and Ureterectomy.—Dr. E. E. Montgomery of Philadelphia said that he wished to report one case. It was that of a woman aged twenty-seven years whose family history was negative as was also her previous history, except that she had had several attacks of what she called inflammation of the bladder. These attacks were characterized by frequent and painful urination and a dull aching pain in the region of the right kidney which at times was relieved by the discharge of large quantities of urine. She has had some night sweats but she has no cough or expectoration. Her appetite is capricious and her weight 118 pounds, a loss of 32 pounds in the past five years. An examination of the urine showed pus and epithelial cells but no blood corpuscles, casts, albumin or sugar. Bacteriologic examination failed to show the tubercle bacillus. On examining the bladder with the cystoscope it was found that the walls were thickened and roughened and that they bled easily. After irrigating the bladder a Harris apparatus for separating and collecting the urine from each side was introduced. Urine was not obtained from the right while the urine flowed freely from the left. Examination of this urine showed it to contain pus and epithelium, but no albumin, casts, blood corpuscles or sugar. Examination for tubercle bacilli was negative, but the streptococcus was present. On making a careful physical examination, a semifluctuating mass was found on the right side at the level of the umbilicus, extending nearly to the median line. A pelvic examination showed the uterus to be slightly enlarged and somewhat movable. On the right side there was a marked indentation between which and the uterus the finger could not be passed. Despite the absence of bacilli in the urine the diagnosis of tuberculosis of the ureter and kidney was made and immediate operation was decided on. An incision was made in the vagina over the line of the right ureter and the tissue pushed back until the ureter was exposed as a hard dense cord as large as the finger. The ureter was then ligated and then divided with scissors, but unfortunately, in accomplishing the division the ligature and the uterine artery were cut. The latter was secured by pressure forceps. The introduction of a catheter through the urethra also demonstrated that the bladder had been opened. The vagina was packed with gauze and the patient turned on her left side and an incison was made in the right lumbar region. This exposed the kidney which was very nodular and contained about a pint of pus. This was evacuated and the kidney then removed. The ureter was then dissected out and the operation was completed by packing above and below with iodoform gauze and suturing all but the upper angle of the lumbar incision, which was left open for drainage. The woman made an uninterrupted recovery. Examinations of the specimens removed showed them to be tuberculous.

Anastomosis of the Ureters with Intestines.—

A full abstract of this will appear later in the Medical News. The discussion was opened by Dr. Ford, who said that he would speak of an interesting case that had lately come under his observation. It was that of a young woman who came to him with the statement that she could only pass about one ounce of urine a day. Examination showed that practically no urine was entering the bladder, but instead it was all being passed through the bowels. The uretero-intestinal anastomosis occurred spontaneously from the passage of a calculus. Palpation failed to reveal the presence of the right kidney, while the left is clearly demonstrable, so he believes that she had only one. For the past year she has been passing about all her urine through the bowel and is apparently in perfect health. Repeated examinations of the urine have failed to reveal any evidences of infection of the kidney.

A Critical Survey of Ureteral Implantation.—Dr. W. Bovée of Washington read this paper and said that injuries of these ducts are apparently becoming much more common. These injuries take many forms, varying from the kinked ureter to the unintentional removal of several inches of the organ. Previous to 1877 there had been but two ways of dealing with a complete section of the ureter. These were the let-alone policy and nephrectomy. It is very probable that but for the popularity of nephrectomy, ureteral surgery would have had a much earlier elaboration. An only kidney was removed but a few years ago in this country, as was disclosed by the autopsy, and anuria existed twenty-nine days before death ensued. Practically all surgeons are now agreed that for severed ureter without much loss of tissue the best procedure is to unite the severed ends. This had been done by four different methods: (a) The transverse end-to-end method has been performed twelve times with two deaths, (b) the oblique end-to-end, once and the patient recovered; (c) the end-to-end, nine times with one death; (d) the lateral implantation or end-in-side, five times with one death. This gives a total of twenty-seven cases in which the cut ureter was directly united and of these four died. After all operations for the repair of the ureter the point of danger is the narrowing of the lumen of the duct by granulation. Uniting the ureteral ends is by far the best method of disposing of the divided ureter whenever this is possible, but it is difficult to decide which method is best suited for all cases. The peculiarities of each individual case and the preferences of the operator must decide each case on it merits and no general rule can be laid down. Considering the other operations for the relief of a divided ureter we find that ureterocystostomy has been performed eighty times. This is a much easier operation than ureteral splicing, which accounts for the number of cases in which it has been done. Of the thirty-seven bladder grafts for injuries of the ureters during abdominal operations, we find that fifteen were done by the intra-peritoneal method at the time of the injury with the result that one case died of extraneous causes and in two cases there was failure. Two were done by the extra-peritoneal plan and the statistics of the remaining number of cases do not state which plan was followed, but one case resulted in a failure. Of the cases done for fistula or other conditions it is found that there were forty-two, of which twelve were intra-peritoneal operations, fourteen by extra-peritoneal operation and in sixteen the method was not mentioned. This operation is especially indicated when in the course of an abdominal operation, section of the ureter in its pelvic portion is made and it is impossible or inadvisable to splice the cut ends. Ureteral fistulæ following operations, difficult labor or forceps delivery and congenital ureteral openings are also indications. Ferguson collected the statistics of 67 cases of ureteral fistula and found that 25 of them were created in parturition, in 16 of which the delivery was by forceps. In 12 cases vaginal hysterectomy was the cause, 2 were due to stone in the ureter and subsequent ulceration, 3 followed abdominal section, 1 was due to traumatism, 2 resulted from pelvic abscesses, 1 was spontaneous (probably tuberculous), 1 from a pessary and 1 from an undilatable stricture of the lower end of the ureter. In utero-vaginal fistula it is only occasionally that cure can be accomplished by vaginal plastic surgery and there is always the danger of relapse from a heavy strain or from cicatricial contraction. The methods of bladder grafting are principally by the abdominal route preferably by the extra-peritoneal method. It is impossible to make an anastomosis between the ureter and the bladder as good as the natural one, because the small muscles attached to the ends of the ureters and lost in the walls of the bladder near the internal meatus can not be utilized. Their function is to draw down the orifice of the ureter when the bladder distends, thus preventing obliquity of that duct through the distended bladder. The observation of careful surgical technic in all operations on the ureter is of the very highest importance, as a very slight infection may render the operation unsuccessful and endanger ascending infection along the ureter. Whenever the ureter requiring grafting is above the brim of the pelvis and ureteral anastomosis with itself or the bladder seems impossible one should consider the advisability of its implantation into its fellow. If this be impossible, then grafting into the bowel will be justifiable. Rectal implantation is indicated in the treatment of ectopia vesicæ, benign and malignant growths of the bladder, requiring the extirpation of that organ, and injuries of the ureter irremediable by ureteral or bladder anastomosis. Many hundreds of experiments have been made on animals to prove the feasibility of this method of procedure, but as a rule they have proved unsatisfactory. The operation has been performed 65 times on man. The recorded mortality has been 18, or a little less than 30 per cent. Six of these died from the shock and severity of the operation for the condition calling for the grafting. In at

least 7 cases death resulted in from 5 days to 2 years after operation, from infection of the kidney, peritonitis or other untoward result of the rectal implantation. In 5 cases the cause of death was obscure and in 2 cases the result is not published. When one considers that of deaths from all causes, 40 per cent. are from subsequent infection, the suspicion that some of the reported successful cases may also later succumb to infection, seems reasonable. This high rate of mortality must necessarily cause anxiety as to the justifiability of the operation and were it not for the excellent work of Maydl, followed so successfully by a number of other surgeons, one might look on the subject with almost condemnation. Only 8 deaths have followed the operations done by his method, a mortality rate of but 21 per cent., and the danger of peritonitis and subsequent kidney infection has been very greatly reduced. There are 5 methods of forming an anastomosis between the ureter and the rectum: (1) by the formation of a fistula between them; (2) by the axial implantation of the ureteral stump into the bowel and its fixation there by either the Lembert or the double-row suture; (3) implantation of both ureters with a piece of the bladder, as by Maydl, Pozzi and others; (4) implantation of both ureters with a small amount of the bladder mucous membrane; (5) by means of apparatus such as that of Calot and Boari. Of these the Maydl operation has given the best results. The skin implantation of the ureter has been advised by some surgeons, but it is believed that the danger of infection is very great and that nephrectomy ultimately would be required. The operation has been done 10 times with 3 deaths. One subsequently required nephrectomy, in 4 the result is not given and in 2 cases ascending infection occurred. These statistics clearly indicate that bowel implantation is a much more favorable operation. The ureter has been implanted into the vagina but 3 times, all of which were successful. But little can be said in favor of this method, for notwithstanding that the three cases in which it has been done were successful, yet it seems to be grafting a perpetual infirmity upon an individual. The ureters have been grafted in the urethra in 5 cases, in 4 of which ectopia vesicæ was the condition, the relief from which was sought. Three of these recovered and two died. This operation has a very limited field and it will never replace the method of bowel implantation.

Migrated Ovarian Tumors.—Dr. George M. Edebohls of New York read this paper by title.

Best Method of Extirpating Fibroid Uteri.—Dr. Howard A. Kelly of Baltimore then read this paper. After describing the various ordinary methods of operating that he had used, he said that he had now adopted a new method of his own. The technic for ordinary cases is to make a vaginal incision, then ligate the ovarian vessels on one side and also pass a ligature around the round ligament. The vessels and the ligament are then divided. Then open the top of the broad ligament and push down the bladder with the broad ligament and so expose the uterine vessels of that side, which are then ligated. The cervix is then divided, exposing the uterine vessels of the opposite side. The uterus, free from the cervix, is then pulled upward and outward exposing successively the round ligament and the remaining ovarian vessels which are then ligated. The cervical wound is closed and the peritoneum of the bladder drawn downward over the wounded area. In exceptionally difficult cases, due to the low origin of a low fibroid choking up the pelvis, and where the ovarian and uterine vessel are so spread out on the upper cervical surface that it is impossible to tie them in mass, a quicker and safer method is to grasp both cornua with strong forceps and then split the uterus and tumors down to the vaginal cervix. The cervix is then divided to the right and to the left, exposing the uterine vessels which are clamped. The uterus freed from the cervix is then pulled out first to one side and then to the other and the ovarian vessels controlled. In this way there is very much less danger from hemorrhage. Precisely the same methods of treatment are applicable to inflammatory cases. After removing the uterus in this way the adherent tubes and ovaries can be dissected out very easily.

Kelly's Method of Removing Fibroids of the Uterus.—Dr. A. Lapthorn Smith of Montreal read the next paper and spoke of the very good results which he had had by operating in the method just described by Dr. Kelly.

Intra-Abdominal Amputation of Uterus.—A modification of hysterectomy, by Dr. F. H. Davenport of Boston, was the next paper on the program. He said that the indications for hysterectomy are well established and its mortality has been reduced to such limits that it ranks with other operations as a thoroughly safe method of procedure. Interest is now centered in the technic. He believes in regard to the relative advantages of the vaginal and abdominal routes that one should be governed by the conditions of each particular case. If the patient be single or near the menopause, the case one of a small or medium-sized non-adherant fibroid and the patient object to the scar that would follow an abdominal hysterectomy, do the operation by the vaginal route. This has the advantage of being quicker, is followed by less shock and the period of convalescence is much more comfortable. On the other hand in a young married woman always perform an abdominal hysterectomy so as to retain the vagina in such position that it will be functionally serviceable. A shortened vagina with a contracted vault is not a desirable condition under these circumstances. There is no danger of the abdominal scar being stretched by a subsequent pregnancy and hernia, while a possible sequela is in these days of careful suturing a very remote one. It is generally best to employ the abdominal route when removing the uterus for chronic inflammatory conditions for the reason that there is usually concomitant dis-

ease of the appendages and the abdominal route gives full opportunity to see the exact condition of all the pelvic organs and so what is necessary may be done under the control of the eye. The technic of hysterectomy may be much simplified for in many cases the body of the uterus alone need be removed, leaving the cervix and perhaps the lowest segment of the uterine body. Where the uterus is chronically inflamed, which keeps up salpingitis and perhaps peritonitis, it is only necessary to obliterate the uterine canal and remove the inflamed tubes to effect a cure. The lower part of the uterus and the cervix will drain freely into the vagina and ultimately undergo atrophy. The essential features in which his method differs from the operation as usually performed is that the uterine arteries are not ligated or, in fact, even disturbed. By whatever method these are treated, whether by tying the arteries or ligating them by including the whole thickness of the broad ligament near the uterus, it is more or less a difficult procedure. The first method involves the opening of the subperitoneal space, thereby increasing the chances of septic infection, and it is good surgery to limit the chances of this as much as possible. The technic of his method is as follows: The broad ligament of each side is seized by a long clamp running from the free space between the ovaries and tubes and the pelvic wall and ending close to the uterine wall at a point a little above the level of the internal os. A second clamp is carried down each side parallel to the first clamp. The clamps having been firmly applied there can be no bleeding. A needle armed with a fine silk ligature is then passed through the angle of the broad ligament between the ends of the clamps and is securely fastened. With a scalpel the uterine tissues are then divided at a level with this suture and in such a way that the anterior and posterior incisions slope downward and meet in the center. This is done from one side of the uterus to the other, a little at a time and the bleeding, which is usually slight, is controlled by the continuous suture which follows the incision. The needle threaded with the silk which has been tied at the angle is introduced into the anterior surface of the uterus just below the free edge, then carried through the tissues and finally brought out at the angle of the wound. It is then reintroduced into the posterior wall and emerges on the posterior surface of the uterus at a point corresponding to its entrance. This is drawn tightly and when enough free space has been gained by the use of the knife another suture is taken. This is continued until the body of the uterus is completely separated and the other side is reached. Then a final stitch is securely tied at the angle of the broad ligament between the clamps. By this method all bleeding is absolutely prevented. It is not necessary to strip the peritoneum off the uterus and the wedge-shaped removal of the uterine body permits the ready and close apposition of the peritoneum. Any little bleeding points on the line of the continuous suture can be controlled later by separate sutures. When the clamps which control the outer segment of the broad ligaments are removed the ovarian arteries may be seized and ligated. There is usually no bleeding from the rest of the broad ligament, but any suspicious points may be tied. This operation has many distinct advantages and it is surprising how often it may be substituted for the more radical one in which the uterine arteries are ligated. Among its advantages are the following: It takes a shorter time to perform; there is usually little loss of blood; it does not open the layers of the broad ligament, and convalescence, as a rule, is short and very free from disturbance.

Dr. Pryor of New York opened the discussion on the three preceding papers and said that when there are several fibroid nodules in the uterus his method is to first tie the ovarian vessels and then split the tumors. Traction forceps to hold the flaps apart are then applied and the tumors removed. The operation is completed by tying the uterine vessels.

Dr. Gordon of Portland, Me., said that for many years he had been employing the continuous suture, carrying it all the way down until the stump was completely covered. In his experience chromicised catgut is a very bad material for suturing as in many cases it is practically never absorbed and in time acts as a foreign body. Ordinary catgut has proven itself to be the best material for suture that he has ever tried and he has never had a case in which silk sutures were indicated, or a stitch abscess occurred. He employs a through-and-through buried silkworm-gut suture which are left in place for from two to three weeks. The ideal method of closing a wound consists in using for sutures only such materials as are easily absorbed.

Dr. Mann of Buffalo said that he believed the methods mentioned by Dr. Kelly and Dr. Pryor are not always the easiest. In those cases where the tumor is held down in the pelvis by the broad ligament, on cutting that ligament and the infundibuliform-pelvic ligament the tumor will come up. Then tie the uterine and ovarian vessels. This is an easier method than that advocated by Dr. Pryor, for the reason that, although the tumor can be removed in a few minutes by his method, the operation is not finished and requires a long time for its completion. It is generally better to tie off the broad ligament before removing the tumor as thereby hemostasis is more complete. The cervix should be dilated and a piece of gauze passed through it, as this will give very much better drainage than if the cervix be removed.

Dr. Baldy of Philadelphia said that he had had a case in which the tumor extended over the bladder. He opened the cul-de-sac posteriorly and performed the same operation as Doyen claimed for his own. Bad cases like these are rare, and such an operation as Dr. Kelly advises is only of use in an emergency. He considers Dr. Pryor's method to be a very dangerous one and not a good routine method of practice. It is an extremely

difficult one for any but an expert, and so should be avoided by beginners. He had seen one operator in doing it tie both ureters and another one tie one ureter. However, it may prove to be a serviceable method of procedure in those cases in which the real character of the tissues are disguised by inflammation.

Dr. Reynolds of Boston said that he had adopted the method of tying the ovarian arteries on each side, then drawing the uterus up strongly, and putting on a clamp on each side one-quarter of an inch above the junction of the uterus and the bladder. He then cut just above the tip of the forceps on each side. A suture was then entered from before backward through the uterine wall and brought out just below the incision on the broad ligament. The same is done on the other side, and a wedge-shaped cut is made in the uterus extending down to the internal os. A suture is introduced to approximate the cut edges and the operation completed by turning the stump.

Dr. Johnstone of Cincinnati said that the personal equation is a very large factor in all operations, and that he believes that Dr. Kelly's troubles are all of his own making. He had had a similar case and after making a vaginal incision tied all of the vessels before doing anything else. The operation was easily completed and there was no bleeding to complicate it. The priority of uterine ligation should be credited to Dr. Polk.

Dr. Harris of Paterson said that the continuous incision is the easiest possible method of supravaginal hysterectomy, as it is not a difficult operation and it is well suited to all cases.

Dr. Kelly, in closing, said that the Guyon method is merely a series of surgical gymnastics, suitable only to very easy cases, as it can not possibly be performed in difficult ones. The bisectional method is especially good in bad cases, as there is no risk to the ureters if one is careful to push down the bladder. He does not believe it good practice to remove small fibroid uteri, and in dealing with those which are of such small size that a clamp can be used, he either performs myomectomy or else does not operate upon them at all.

The President's Address.—This was delivered by Dr. George J. Engelmann of Boston. After reviewing at length the history of the Society since its foundation and the progress made in gynecology and obstetrics during that period, he said that he would direct the attention of the Society to the subject of menstruation. This is always a period of danger, a period of highest susceptibility, more dangerous to the nervous organism than to the physical structures. It is in puberty and the formative period that this all-pervading function which controls woman's entire being is readily moulded and controlled by surrounding conditions of all kinds. Puberty or the establishing of functional life is swayed by the most varied conditions; race and climate influence its advent, but equally, if not more so, is it controlled by social conditions and mental status. It is most important to note the effect of mental activity. Many investigators have shown that the wealthy and the city-born are more precocious than their poorer or their country-bred sisters, but my own investigations more especially indicate the influence of mental stimulus. Thus, out of 2315 patients who came under my observation in St. Louis dispensaries, the average age at which menstruation commenced was 14.24 years, while Dr. Chadwick of Boston has found much the same, for in his 2500 cases the age was 14.3 years. In 697 cases from a consulting practice throughout the Southwestern States, country-bred women, the average age was 14.3 years. The average in 800 cases among Boston's highest class working-girls was 14 years. Among the high and normal school girls, the 750 of whom statistics were collected gave the average of 13.8 years. In 1200 college girls the average was 13.5 years. Neither birthplace nor parentage influences the development of the girl and the appearance of puberty, as do the surroundings of childhood and early youth, which give a variation of one year, as noted in the 5000 cases which have been under observation. The author emphasized the susceptibility of the function to mental influence and likewise the controlling influence of the function upon the anatomical, physiological and pathological status of the growing girl.

(To be Continued.)

REVIEWS.

A Pocket Medical Dictionary. Fourth Edition, Revised and Enlarged. By GEORGE M. GOULD, A.M., M.D. Philadelphia: P. Blakiston's Son & Company.

THIS is a convenient little book to have at one's elbow. The text is clear, the pronunciation of each word is given, and the definition is concise and comprehensive. In this new edition a large number of additional eponymic clinical terms have been introduced, the dose-table has been enlarged to include doses and drugs recently introduced, and a number of inaccuracies in former editions have been corrected. It has flexible covers and gilt edges.

Progressive Medicine, March, 1900. Quarterly Digest of Advances in the Medical and Surgical Sciences. Edited by HOBART AMORY HARE and CHARLES ADAMS HOLDER. Volume I, March, 1900. Lea Brothers & Co.: Philadelphia and New York.

THE first volume for the second year of this periodical, containing, therefore, the first repetition of the review of the subjects treated, shows that the original purpose of the editor and contributors is being kept thoroughly in view. Progressive Medicine supplies a very personal authoritative discussion of the latest subjects of interest in medicine, surgery and the specialties.

Dr. J. Chalmers Da Costa's review of the various incisions suggested for the radical operation for cancer of the breast is illustrated in a manner to make this subject extremely clear. The success of Halsted's method of operation and the number of adherents it has gained among prominent surgeons all over the world are well brought out. The place of Beetson's method, the removal of the ovaries and the administration of thyroid extract for inoperable carcinoma of the breast, is made very clear. That some good is accomplished by this method there is no reason to doubt. The ultimate effect of the treatment is, however, as yet entirely unknown.

Acute articular rheumatism is very properly included among the infectious diseases. Dr. Frederick Packard makes a plea for the more careful use of the word rheumatism. Too many vague painful conditions are grouped under this term. The use of such expressions as gonorrheal rheumatism, scarlatinal rheumatism, pyemic rheumatism, is deprecated because they give a false idea of the nature of the process at work. The conclusion is suggested that the near future will demonstrate acute articular rheumatism to be really a modified pyemia. It is not, however, so much the actual presence of micro-organisms in the blood which causes the manifestations of rheumatism as toxic principles of a chemical nature whose presence sets up symptoms of the disease. The humoral theory that attributes acute articular rheumatism to the excessive formation of lactic acid in the blood is set down as utterly unconfirmed. It is not impossible, however, that a certain amount of this substance is produced during the course of the rheumatism and causes some of the arthritic symptoms. But it is a secondary not a primary factor in the rheumatic condition.

Dr. Blackader has a very timely review of the affections of the alimentary tract in children and of the modification of milk for infant-feeding during the trying summer months. Variations in the amount of the different constituents of cow's milk during the uncertain feeding of the grazing period—the spring and summer—are especially dwelt on. The question of the addition of cereals to milk is treated from the standpoint of the new interest that has been awakened in this subject during recent years. There seems now no reason to doubt that the addition of cereals, instead of being harmful, is always beneficial. Nitrogenous elimination in the infant is always decreased by the administration of a certain amount of carbohydrates. Heubner's investigations emphasize the importance of non-nitrogenous food because it favors growth by protecting the albumens from useless decomposition. This is a new idea and one which shows that pediatrists now recognize that the problem of infant-feeding is no longer the simple chemical question of digestibility but that there are a number of important biological factors that enter into it.

Other things in the volume might be mentioned, such as Dr. Randolph's review of mastoid complications and sinus thrombosis, Dr. Turner's discussion of the use of new therapeutic agents in the nose and throat, and Dr. Haktoen's review of the theory of antitoxin and of the recently-discovered pathogenic micro-organisms; but amidst so much that is good the reviewer is limited in selection.

The Year-Book of the Nose, Throat and Ear. Nose and Throat edited by G. P. Head, Professor of Laryngology and Rhinology, Post-Graduate Medical School of Chicago; The Ear Edited by A. H. Andrews, Professor of Otology, Post-Graduate Medical School of Chicago. Chicago Medical Book Co., 1900. Pp. 274.

The editors have in this work abstracted the special literature of the past year and have grouped it under appropriate anatomical and pathological headings. Thus, with the aid of the fairly complete index a large amount of useful matter is placed within easy reach of the general practitioner. The foreign journals have been freely consulted, and special articles have been devoted to some of the newer remedies, such as suprarenal extract, heroin, and orthoform. One finds here the different methods in vogue among specialists the world over. The remedies for tuberculous laryngitis, for instance, include scarification, curetting, electrocautery, submucous injections of creosote, intratracheal injections, lactic acid, formic acid, formaldehyd, orthoform, iodoform, para- and ortho-monochlorphenol, guaiacol, ichthyol, absolute alcohol, lanoline containing 3 per cent. naphtalin and oxidized tubercle toxins. In the body of the work a fair number of useful prescriptions have been included. Although the editors are themselves specialists they rarely express opinions of their own, but leave the reader to his own summing up of the literature, and his own choice of remedies.

THERAPEUTIC HINTS.

Hot Local Baths for Infected Wounds.—*Platonov* uses this treatment with excellent results; the secretion of pus diminishes, the healing process is quickened, and the immediate effect is soothing. He finds it best to give the baths just before renewing the dressing. The temperature should be from 90° to 104° F.

Varicose ulcers also improve under the bath treatment; the sloughs are thrown off more rapidly, and the secretion loses its fetidity by which it is often characterized. In case of infected wounds cicatrization is hastened; this is, however, not true of varicose ulcers.

For Chancroid.—*Frolov* highly recommends the biniodosalicylate of soda in the form of a 2 per cent. ointment for recent cases, or 10 to 15 per cent. in neglected cases. It acts as a cautery, gradually destroying the diseased tissue at the periphery of the sore, although it is almost or even entirely painless, and possesses the added advantage of being odorless.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXXVI. NEW YORK, SATURDAY, MAY 26, 1900. NO. 21.

ORIGINAL ARTICLES.

CYSTITIS PAPILLOMATOSA.

BY FREDERIC BIERHOFF, M.D.,
OF NEW YORK;
ASSISTANT IN THE DEPARTMENT OF GENITO-URINARY DISEASES, BERLINER ALLGEMEINE POLIKLINIC; ASSISTANT AND CYSTOSCOPIST IN THE GYNECOLOGICAL POLICLINIC OF DR. R. KNORR, BERLIN, GERMANY.

THIS condition occurs in the female as a form of chronic cystitis, and may present the clinical picture either of the catarrhal (usually called "irritable bladder") or of the suppurative form. Its symptoms are frequency of urination, accompanied by more or less pain, and tenesmus, the urine passed being clear, or turbid. Bleeding, which is usually a characteristic symptom of true vesical papilloma, does not occur spontaneously, although it may follow instrumentation, as the tender, hypertrophied, inflamed membrane bleeds very readily. Its seat is at the trigone, which it usually covers, and it may extend over into the urethra, from which at times it appears to start. Its villi, or papillæ, spring from an inflamed base and are discrete.

On cystoscopic examination, the entire trigone is found to be the seat of a well-marked inflammatory process, the mucous membrane, from the ligamentum interuretericum to the sphincter internus, being of a deep red color, while the surface has a grayish-red, cumulous appearance, the result of the diminished power of reflection of the inflamed membrane. The rest of the bladder is normal. If the window of the cystoscope be brought near the surface of the mucous membrane, this cumulous appearance changes so that the suspicion is aroused that one has to deal with a papillary growth. Viertel[1] stated his belief that, in some cases of chronic cystitis, the satiny appearance of the inflamed mucous membrane was due to the beginning formation of papillæ. This suspicion may become a certainty by the employment of the following simple procedure, which I employed to remove the doubt as to the nature of the growth in the appended cases: The uretercystoscope is armed with a ureter-catheter, and inserted into the bladder (in my work I employed the Nitze-Albarran cystoscope), so that the window lies directly over and close to the inflamed area; the catheter is then gently laid diagonally upon this surface, or is passed over the surface at an agle. It will at once sink into the mass of papillæ, or pass between them, and the individual papillæ will stand out distinctly as discrete, rosy-red tongues, against the deeper color of the catheter.

The following cases are illustrative of this condition:

Case I.—Frau S., aged fifty-two years, widow. Her only complaint is of frequency of urination, the act being accompanied by pain, and the stream of urine is, at times, interrupted. The urine is normal.

Cystoscopic Examination.—At the trigone, an area of diffuse redness, covered with papillomalike excrescences. Distortion of the left side of the bladder. Otherwise normal. Declines treatment.

Case II.—Frl. Marie P., aged twenty-six years, July 20, 1899. For some months the patient has complained of frequent and painful micturition (is awakened once during the night by the urgent desire to urinate), the act being preceded and followed by tenesmus and accompanied by burning. She has also noticed a slight urethral discharge. Has never had gonorrhea. Menstruation regular; patient habitually constipated. Says that, during childhood, she suffered from renal disease for a long time. Urethal secretion is of mucous character. Microscopical examination reveals few leucocytes, abundant epithelia, diplobacilli, diplococci (not gonococci), streptobacilli and streptococci. Urine turbid, acid. Filtered, contains albumin. Sediment contains many leucocytes, epithelia, amorphous urates.

Cytoscopic Examination.—The trigone and lower rear and side walls are inflamed. Trigone, including the sphincteral margin, the seat of a papillomatous new growth, upon a broad base. At one point the surface is covered by a blood-coagulum.

For the present, irrigations with boric acid solution. July 31st: On the 25th and 26th inst., injections of nitrate of one-per-cent. silver solution. Urine is still slightly turbid, acid, and contains a trace of albumin. Pain and tenesmus have disappeared. Patient urinates at normal intervals. Edema of the lower extremities. Further cystoscopic examination shows decided improvement. New growth diminished in prominence. Further treatment.—In addition to irrigations, acetate of potash, 10 grains, twice daily in water.

August 2d: Urine decidedly turbid, acid; contains albumin. Edema less marked. From this time on, injections of one-per-cent. nitrate of silver solution daily; later every second day.

August 4th: Catheterization of ureters. Urine from left kidney perfectly clear, slightly alkaline, free from albumin; that from right kidney entirely clear, alkaline, contains trace of albumin. Boric acid, 3 grains three times daily, in water, was used to replace the acetate of potash.

August 11th: Much improved. Urination normal. Edema disappeared.

August 18th: Cystoscopic examination reveals dark-red area on the lower, left portion of the trigone.

September 4th: Condition normal. Urine normal; cystoscopic examination shows a normal bladder. An endoscopic examination shows some diffuse redness of urethra. All treatment was suspended.

September 11th: Condition normal. Urine normal and free from albumin. Discharged cured.

Case III.—Frau T., aged thirty years, September 7, 1899. Retroflexio uteri, perimetritis. Periods of frequent, painful urination alternately with the normal state. Patient, during the abnormal periods, must urinate "every few minutes" during the day (not during the night) and each time only a few drops of urine are passed. The act is accompanied by cutting and burning pains, and preceded and followed by tenesmus. The urine is normal.

Cystoscopic Examination.—Entire trigone covered with rosy-red, translucent papillæ, springing from an inflamed base. Injections of nitrate of silver solution, beginning with one-fourth of one-per-cent. were employed.

September 12th: Improvement in symptoms. Urinates at normal intervals. Urine is normal. Later withdrew from treatment.

Whether this condition is an early, developmental stage of the broad-based, vesical papilloma, or only a condition of extreme hypertrophy of a chronically inflamed mucous membrane, I am not prepared to say with certainty, as I have been unable to examine the condition histologically. I am inclined, however, to look upon it as a form of chronic cystitis.

In many cases such as these, which rest upon the border-line, the differential diagnosis between cystitis and vesical tumor is exceedingly difficult. In this connection Casper[2] says that in many cases of chronic cystitis the vesical mucous membrane even grows into tumor-like ridges; that "the difficulties in diagnosis are greatly increased when the growth is comparatively flat and the projections upon the mucous membrane relatively pronounced. It may become practically impossible to determine whether the object is a tumor, or only a prominence of the vesical mucous membrane. In reality, these things are at times identical, only bearing different names. We know tumors which represent nothing else than marked papillary excrescences of the submucosa, covered with greatly thickened epithelium." He also mentions the fact that frequently, although not in all cases, the tumor-like formations are circumscribed, while the areas of swelling and hypertrophy of the mucous membrane are diffuse, and that, while the latter are usually multiple, this is not so often the case with tumors. Kolischer[3] mentions a form of "granulating cystitis," in which the entire bladder-wall is covered with regular, light-red granulations, and has the appearance of coarse, red satin, and that, at times, the single granulations are very large. Güterbock,[4] in dealing with the pathological anatomy of chronic cystitis, mentions the fact that at times the mucous membrane is hypertrophied and the folds are enlarged so that they form condylomatous, less often polypoid excrescences, which may be differentiated from real tumors by their greater multiplicity and their transient character. In describing new growths of the bladder, he says: "The most frequent form is the simple, papillomatous growth—which is really differentiated from the before-mentioned inflammatory growths (in chronic cystitis, as mentioned) only by its somewhat greater persistence. It seldom occurs singly, is usually multiple, usually affects the region of the trigone, and occurs both pedunculated and broad-based, etc." White and Martin,[5] in describing vesical papillomata, state that: "They may form a villous surface, made up of closely-grouped, fine papillæ springing from the mucous membrane, etc;" while Martin and Taylor,[6] in describing chronic, catarrhal cystitis, state that: "Often the epithelial proliferation may be so active that villosities are formed—minute excrescences composed of a capillary stalk surmounted by epithelium, and bleeding readily. Mucous polps are also seen; in these the vascular elements are less pronounced, while the epithelial overgrowth is such that they quite resemble papillomata." Herring[7] speaks of the benefit to be derived from the use of nitrate of silver solution in the treatment of vesical hemorrhage due to papillomatous growths; but, unfortunately, makes no mention of cystoscopic examination of his cases.

A perusal of the descriptions given by the different authors quoted above proves that, as Casper stated, much confusion exists in the differential diagnosis between chronic cystitis and vesical papilloma, and a comparison of the above cases with the diagnostic points mentioned by these authors demonstrates that they might be classed both as chronic cystitis and as tumor. Since the hypertrophic process, however, occurred invariably upon an inflamed mucous membrane, and as, in the one case which could be treated to the end, the papillæ disappeared with the cure of the inflammatory process, I am inclined to look upon the process as a chronic cystitis. The improvement under similar treatment that has attended other cases confirms me in this opinion.

I am indebted to my friend and colleague, Dr. R. Knorr, for the permission to make use of the cases quoted.

MEDICINAL AND NON-MEDICINAL REMEDIES; WITH POINTS ON HYDROTHERAPY, DIET, AND MASSAGE, IN CERTAIN DISEASES ATTENDED WITH HIGH TEMPERATURE.

By CHARLES E. PAGE, M.D.,
OF BOSTON.

It is a promising sign of the times that more individuals in the profession of medicine are becoming somewhat skeptical as to the virtues of even the most vaunted of the potent drugs in common use in the treatment of disease, than at any previous time in the history of medicine, and giving more thought to the study and practice of more natural methods.

"The history of medicine illustrates the fact that modern therapeutics only attains perfection when it approaches most nearly to the teachings of Hippocrates," says Dr. Edwin W. Pile, Fellow of the New York Academy of Medicine, in a recent article. "In most cases of sickness had simple water been administered, and those natural means which automatically operate to maintain health been employed, the sick would have been benefited and the doctors' reputation improved." Herein may be found, in great measure, the secret of the success of many empirics; these men having followed more nearly than have the grand army of regulars the teachings of the "Father of Medicine."

In an address before the Reading Pathological Society (*Lancet*, January 6, 1900) on Uric Acid, J. F. Goodhart, M.D., LL.D., Consulting Physician to Guy's Hospital, says: "For myself, I cannot but think that had it not been for our eagerness to get hold of something to 'treat,' the uric-acid theory that is dominant at the present time would never have become the fetish that it has.

"One of the weaknesses of our profession is this, that we incline to do too much; and in so doing overtreat disease. Do not you find, you, my hearers, who have come to middle age and passed it, that one of the chief pleasures of your position is that of having a firmer conviction of the self-righting power of the human body? Let it alone; give it time, rest, freedom, fresh air. It must be so; for I hear it said on all sides of the ripe and mellow go-aheads of but a few years ago, by their juniors, the go-aheads of to-day, how much less active they are than they were when they began to make their names. Yes, they now wait and watch. Alert still, but with a chastened judgment that is well worth study. And surely this tells us that their experience has taught them to take an ampler view of the buoyancy and tenacity of life; that they have seen that many of their earlier efforts were petty interferences with greater power that tends almost inexhaustibly towards health, and 'trusting the larger hope' they have shed off the immaturity of meddlesomeness."

But still, as it seems to the present writer, this savors too much of the faith-cure to be altogether soothing to the mind of the perplexed student, however desirous he may be to mend his ways. Of course, it is vastly better, when in doubt, to do nothing than to do things that are harmful; but in all the length of Dr. Goodhart's address there was scarcely a hint as to physiologic treatment of disease. Throughout the profession, regular, empiric, or what not, there is a proneness to "harp on one string," so to say; that is, to treat disease with drugs alone (too common a practice with the regular profession); with hydrotherapy alone (the habit of many empirics); with massage alone (now posing as osteopathy); with faith in *vis medicatrix naturæ* alone, the scheme of many in the regular profession who have lost confidence in the virtues of drugs, but who have failed to learn the lessons taught by the success of the pure and simple hydropaths, osteopaths, and above all of the hygienists who employ both of the foregoing methods together with many other helpful procedures, as therapeutic fasting, sun-baths, air-baths, etc.

The prince of physicians is he who is expert in all of these potent measures for aiding the disordered organism in its efforts to regain that just balance which we term health. Were I to be shut up to a choice of one only method out of all those above named, I would assuredly and without hesitation adopt hydrotherapy in the treatment of all diseases, chronic or acute; this would be my first choice; drugs, alone, my last. Between these two, for an active and potent method, we have massage, and in a wide range of disorders, and when skilfully applied, no well-informed physician will lightly estimate its value. Beyond a doubt we often take the risk of losing a patient to the masseur when, in loyalty to our client, we call in the aid of an expert in this treatment; and this, too, when he means to be loyal to his chief. For rightly applied his work is so beneficial, and to the patient's mind apparently the only thing needed, that it will often happen that the latter will get in the way of employing this form of treatment without consulting the physician who has been honorable enough to take this risk in his desire to bring in every possible aid to hasten a cure. I am aware that many physicians have felt compelled in self-defense to refrain from recommending massage on this account. For myself, I would rather lose any patient into the hands of a masseur now and then, than take any chance of losing him into the hands of the undertaker.

It is a glaring, if not a criminal, fault of our medical schools that except in the most superficial way nothing is done in the way of teaching hydrotherapy or massage. Hydrotherapy and the medical schools is a question which of late has exercised the minds of a few of our leading medical men. The editor of the MEDICAL NEWS recently discussed this topic at considerable length and most intelligently. The views of several medical men were quoted, the text being the essay of Professor Putnam of Harvard University on "Hydrotherapy: Its Scientific Basis." In the

discussion following the reading of Professor Putnam's paper, Dr. Coggeshall insisted that "it is disgraceful that students should be allowed to graduate from our medical colleges with practically no systematic teaching in regard to non-medicinal therapeutics;" and Dr. Rogers remarked jocosely that "medical colleges ought to cease graduating men who don't know a Scotch douche from a hot Scotch!" Kussmaul was quoted as follows: "Of hydrotherapy the young physician knows almost nothing. Here is a great gap in the education of our physicians; here is the real cause of his inability to cope with the empiric for the favor of the public!" And yet we are fond of sneering at the empiric's work, when we should be quick to recognize its value and hasten to profit by it. Another pregnant sentiment, that of Prof. Credé of Leipzig: "If physicians were better versed in these branches (hydrotherapy, massage, etc.), the field of operation of many quacks would be greatly curtailed." That is to say, if we were as well informed as the empirics we would do as good work and drive them from the field; for the quack is tremendously handicapped in many ways: "The laity generally require their doctors to be labelled 'safe' [that is, regular]," says the *British Medical Journal* for January 13, 1900, in an editorial on "Information *vs.* Education." The *Journal* justifies the criticism that has been made that at the end of five years medical students, having gained their diplomas through cramming, go out as assistants, having been taught the latest pathologic theories, but no common sense;[1] that they are stuffed with knowledge but cannot learn. Their real training does not begin until they are delivered from their teachers and thrown on their own resources. "In this," continues the editor, "we believe they (the critics) are right. The examiners feel that the public is only saved from indiscriminate slaughter if the student knows the three actions of the pancreatic juice! The examiners therefore will continue to demand a store of information, and students will in consequence postpone until after their diplomas the acquirement [reacquirement?] of that common sense whose absence we all deplore in one another."

But, does all this mean the banishment of drugs from our therapeutics? Not necessarily by any means; although it certainly is the conviction of many of the foremost medical men of our day, that as drugs are employed by the great proportion of medical men, practically as an exclusive means in the treatment of disease, they do vastly more harm than good. Let us consider some of the ways in which certain drugs injure the prospects of recovery. Take, for example, a typhoid fever patient who, in spite of lack of appetite, in face, even, of a loathing for food, and whose tongue is heavily coated, clearly indicating a stomach devoid of gastric juice, and an utter impossibility of food-substances being dissolved, preserved, and fitted for intestinal digestion; intestines, indeed, loaded with fermenting or putrescent aliments—a patient in this deplorable state, we will say, becomes a victim to still further forced-feeding till his temperature is forced up to what is considered a dangerous point. In such a case the average physician is apt to give heavy doses of, let us say, antipyrine, which may cause a sudden drop of the temperature to near, possibly below, the normal. By this means a heavy blow has been struck at the vitality of the patient, a blow at the very force which it is our first duty to exalt in every possible way. While it is doubtless safe to say that by means of early therapeutic fasting, the profuse drinking of fresh, cool water for a few days, the condition above described would have been avoided, still the physician may be called to a patient already thus diseased; something surely needs to be done in the way of active treatment.

A case of this kind came under my care not long ago. The patient, a man about thirty years of age, had been constantly fed with milk, beef-tea, switched eggs, etc., and well drugged, from day to day, although the food had been taken under protest. His temperature was 104.5° F. There was some delirium; great distention of the bowels, and severe pain. I at once gave him the benefit of a Brand bath, in water at 67° F., for fifteen minutes, with active friction of the skin during every moment he was in the water; and several pitcherfuls of cool water were poured over his head meanwhile. No part of this procedure was designed for the purpose of abruptly "downing the temperature," be it understood,[1] but for its bracing effects on the heart and nervous system. Directly after returning the patient to bed, without drying the skin or returning the night gown, and having the feet and legs well manipulated by a skilled masseur with his hands moistened with hot olive oil until the extremities glowed with warmth, I administered fifteen grains of Riedel's salipyrin. The bath completely restored the patient from his delirium, and he went off into a restful sleep of an hour. On waking his temperature was found to be 102.5° F. I did not take the temperature immediately after the bath, but from past experiences I have no reason to believe that it was much, if any, less than when he entered the bath. From this time I employed the damp bandage (two-ply coarse linen towel, wrung tightly from ice-water, with two-ply, same, dry, outside) as the only hydrotherapeutic procedure, except so far as cooling the head with cold compress to the fullest soothing degree, whenever it was required for the patient's comfort. This procedure, the cold compress for the head, is not a light, damp rag, nor

[1] The late Prof. John Kirk of Edinburgh used to say of medical students that they entered college with plenty of common sense, and departed with it pretty much "educated" out of them; and that it took the average bright lad half a lifetime to unlearn the mistaken teachings of the medical school, while the ordinary ones never recovered.

[1] Dr. Brand, himself, who for thirty years or more did so much to popularize this measure, which in his hands, and in those of Vogl, Juergensen, Wintermitz, etc., reduced the death-rate in typhoid fever practically to nil (one series of cases numbering 1223 by this method, treated by the three first named physicians, in hospital and private practice, resulted in mortality of 1 per cent.), died lamenting the fact that physicians generally completely misunderstood the theory upon which this bath was employed by him and his immediate confreres.

even the folded towel put on and left to become over-heated; but the latter is to be firmly pressed about the head, the hair being well wetted first, and freshened as often as it gets heated up. The same is to be said of the "damp bandage," which should extend from the pit of the stomach to the hips, and freshened every hour, or two, or three, as the case may be, according to the rapidity of heating up. These two procedures are perhaps of all those at our command of the most universal application, giving the greatest degree of comfort in an endless variety of disorders accompanied with high temperature. Several years ago, when my eight-year-old son was a babe of three years, the little chap was wakeful and uneasy one night after being put to bed, and kept crying out in apparent distress. I went to him, and for the moment my presence seemed to suffice for his needs, and with a soothing word of good night I turned to come away. I had not crossed the threshold of his chamber-door when he cried out again in great grief. Returning to his bedside I asked, "What do you want, Charlie?" At the top his voice he bellowed out, "I want a cold pack!" Well did he know from former experiences the delightful effect of the damp bandage. Applying the bandage deftly, as quickly as it could be managed, I straightened out his little nightgown and brought the bedcovers nicely about him, and he was in a sound sleep within one minute of time. Not another movement or note from him for the night. I visited him a couple of hours later, and finding the inner, damp folds getting somewhat hot, I quietly removed the bandage without his waking; he slept quietly the balance of the night, and awoke fresh and bright in the morning. He had suffered from an attack of indigestion, was hot and uncomfortable, and the right remedy worked like a charm.

But to return to my fever patient. A full cool water enema brought away a vesselful of milk-curds and all manners of putrescent food-substances, to his great comfort; directly the skin became moist, and he dropped off quietly into a sleep lasting a couple of hours, from which he awoke refreshed. He had from this time on for the next ten days what I regard as the true "physiologic diet" in fever, *viz.*, water, fresh and soft, and cool, not ice-water. Occasionally he was given moderately hot water, and altogether he took from three to five pints every twenty-four hours. The fluidity of the blood was thus made to approach the normal point; the urine, before scant and high-colored, became more profuse and natural in complexion; sordes disappeared; the tongue began to clean, and he was very shortly a "comfortably-sick" man, with small need of much attention from any one.

Occasional half-doses of salipyrin during the first few days was all the medicament employed, and seemed to work entirely to my satisfaction, causing no discomfort to the patient, whose temperature kept down near 101° F., a mild fever which might properly be considered a normal adjustment to the bodily condition. He went on without a skip from convalescence to perfect health. In accordance with my instructions, that "when he thought he could take a piece of stale Graham bread for 'pie' he might try it," about the eleventh day he began eating. He was allowed a moderate portion of this bread twice a day for a couple of days, dry on the tongue, so to say; that is, he chewed every mouthful until it was semi-fluid with saliva alone. Water was given *ad lib.* whenever the stomach was empty. Shortly after this he was allowed moderate portions of stewed prunes as dessert; but the greatest caution was taken to prevent overfeeding. No tonics to stimulate appetency; no tempting dishes were placed before him or talked about, and the results fully justified the entire management of the case.

During the present winter I have had a number of cases of grip in charge. I have come to regard this disease as one of flannels and food; of overclothing, chiefly. Of course, overfeeding is a universal habit. During "unseasonably warm weather" in winter, or, in fact, indoors at any season, the wearing of heavy inner and outer clothing is in the highest degree unhygienic. In all my cases this winter I have stopped all feeding until convalescence was established, giving moderate doses of salipyrin, with plenty of cool water, usually aborting the disease in from three to six days. I employ the cold compress freely over the chest for any indication of pneumonia. During the first twenty-four to forty-eight hours in most of these cases I employ the damp bandage as above described, and always with comfort to the patients. In a number of cases I have employed as a beginning of the treatment the hot foot- and leg-bath to the point of provoking a full sweat, as follows: Have the patient's feet and legs well up the calves in water at about 100° F., having some portion removed and replaced with boiling water from time to time, making the water a little hotter and hotter, as the patient can bear it without discomfort. In thirty to forty minutes he is in a profuse sweat; then he is sponged all over with dilute acetic acid (1 to 16) and put to bed. He is sufficiently, but not over, wrapped, and he is ordered to have his sleeping-room windows well open throughout the night. In all these cases, too, it is found that well-applied massage is both soothing and curative. Nothing will more speedily drive away all semblance of the shivery, shakey, disagreeable feeling so common in these cases.

154 Tremont Street.

ORGANOTHERAPY IN TABES AND OTHER NERVOUS DISEASES.

By MARTIN A. H. THELBERG, M.D.,
OF NEW YORK;
LATE ANALYTICAL CHEMIST; LATE HOUSE-PHYSICIAN IN THE CITY HOSPITAL.

Notwithstanding the widely different opinions expressed by undoubtedly keen, painstaking and otherwise reliable observers in regard to the employment of testicular extract in the treatment

or locomotor ataxia and other nervous conditions, the writer was tempted to try its effects in a case of tabes in its initial stages, in which other curative and palliative measures had failed to relieve the especially distressing incontinence, bladder and rectal crises, etc., and also in a case of Parkinson's disease.

The literature on the subject is certainly attractive in its excessive praise or condemnation of the remedy, and, even if "suggestion" is the prime factor in the majority of cases cited as benefited by the testicular fluid, the fact still remains that careful observers in carefully conducted trials have found cure or amelioration.

The theory of Dana regarding tabes is that "the specific toxin, enclosed within the subdural and subarachnoidean spaces of the cord and cranial cavity, acts especially on the highly organized posterior spinal ganglia, which, with their special vascular supply, furnish much more opportunity for mischief than the non-vascular anterior roots." If we accept this or any other toxin theory, what could give a more attractive field for the antitoxic possibilities of sero- or organotherapy? That the pathologic conditions already existing should be restored to a former, normal state, none could expect, while again the arrest of an advancing pathologic process is certainly not beyond reason.

One does not need Brown-Séquard's scientific enthusiasm to recognize as a fact beyond doubt that a properly prepared testicular extract certainly has a powerful effect on the nervous system. It is, again, hardly possible to say whether this is brought about—as another eminent enthusiast on the subject, Professor Poehl of St. Petersburg, claims—by its acting "as a ferment in textural respiration, oxydizing the products of retrogressive metamorphosis, freeing the textures from an accumulation of the products of malassimilation and reducing an abnormal, diminished alkalinity of the blood to its normal state." That Charcot found no cure of ataxia from the employment of orchitic fluid in his clinics is no proof against the possible antitoxic properties of a properly prepared testicular extract to the tabetic toxin. Nor must we necessarily coincide with Collin's view, that "the annals of so-called testicular therapy constitute a memorial to the fatuousness of man." We need only to recall the persistent and prejudicial opposition, as well as visionary and hyperenthusiastic favor that diphtheria and other antitoxins called forth to recognize that cool and impartial judgment must be the starting-point in every experiment. It is therefore refreshing to note the moderate and modest remarks on the subject in Foster's excellent "Reference-Book of Practical Therapeutics," from which condensed and reliable information has been drawn that, notwithstanding the fact that in none of the author's own cases had any especial benefit been noticed in tabetics, still he did not feel justified in condemning as useless a remedy that had been found of value by so many reliable observers.

Before relating the very typical case of locomotor ataxia in which the writer has found pronounced benefit from the hypodermatic use of testicular extract, a hasty glance at the literature of the subject may not be amiss.

Dana says in his "Text-Book of Nervous Diseases" that "there is some evidence that the extract of the testicle has a tonic effect on the nerve-centers."

In Loomis-Thompson's "American System of Practical Medicine" we find on page 209: "Suffice it to say that apparently reliable testimony is on record of cases of tabes arrested by testicular fluid, and very numerous examples of marked symptomatic improvement. Recent experiments in a series of nineteen cases of tabes at the Infirmary for Nervous Diseases in Philadelphia by F. S. Pearce, under the direction of S. Weir Mitchell, tend to support the claims made by the French for this remedy. Every effort was made to exclude the effects of suggestion, the patients being unaware of the nature of the remedy employed."

Dr. Paul Gibier in the *New York Therapeutic Review*, Vol. II., No. 2, claims that "in the four cases of tabes treated by him with testicular extract all showed improvement in general health. In one of the cases the bladder regained its power, constipation disappeared and walking improved. In another the weakness lessened, standing became possible with the eyes closed and diplopia disappeared. In still another the severe pains were relieved, sensation was very much improved and walking became much better."

F. S. Pearce in the Medical News, August 22, 1896, relates forty cases—thirty males and ten females—suffering from locomotor ataxia, sclerotic changes in the cord, neurasthenia, and the like, treated with from twenty to thirty minim average doses of Brown-Séquard's fluid. Improvement was noted in nervous diseases of a chronic nature and consisted in a general stimulation as well as an increase in the sexual sense. Foster in the "Reference Book of Practical Therapeutics" says: "One case of locomotor ataxia treated by means of the orchitic fluid by Dr. Depoux of Paris and one by Dr. Gilbert of Havre certainly showed remarkable improvement, which was maintained when the report was made, nearly a year after the treatment had been discontinued. In none of the cases of locomotor ataxia treated by means of the orchitic fluid have the knee-jerks returned, so far as I have been able to learn." White and Wilcox, in the third edition of "Materia Medica," say under organic extracts that "favorable reports of the use of testicular juice in many hundred cases of organic nervous disorders have been placed on record."

As for the chemistry of spermin, Dr. Virgil Coblentz tells us in "The Newer Remedies" (1899) that it is "a base, belonging to the class of leucomaines, obtained from the seminal fluid of animals. Also found in various glands and organs of the human body. A readily soluble, crystalline substance, which is usually obtained in

the form of the hydrochloride." He adds, in regard to the especial preparation employed by the writer, that it is "a solution of the hydrochloride of the base spermin, $C_5H_{14}N$, which occurs in the testicular fluid and the fluid of other glands, and is employed in all diseases caused by autointoxication, such as neurasthenia, tabes, etc. It exerts a powerful tonic and stimulating action upon the nervous system."

Regarding the physiologicochemical action of spermin little, or nothing, is positively known. A most attractive and certainly very logical and scientific theory in regard to an organic extract is the one advanced by Dr. Althaus in the *Lancet*, December, 1893, in reference to alphacerebrine, where he suggests, that its action upon the nervous system may be due, first, to the injection of a highly specialized pabulum of nervous matter: secondly, to the decomposition of the lecithin and protagon, which it contains, through the alkaline blood into choline, glycerophosphoric acid and stearic acid. Choline, by reason of its oxydizing action on the blood, acts as an antitoxin, while the value of glycerophosphoric acid as a nervine is well known. Professor Senator found also that "spermin reduces an abnormal, diminished alkalinity of the blood to its normal state," thus, as Poehl claims, "preserving the system from autointoxication and acting as one of the factors of natural immunity."

No matter *how* spermin acts, however, the main question to be considered is: Does it act? The answer to this must without doubt be in the affirmative, at least in the one case of tabes and one case of Parkinson's disease in which the writer has employed spermin hypodermatically in the form of Poehl's solution, and I shall cite the tabetic case in detail, so that no doubt can be had in regard to the diagnosis.

Case I.—Mr. X., aged forty years. History of specific urethritis and syphilis thirteen years ago, for which he was under the able treatment of one of our most eminent specialists for about three years. During that time inunctions and other mercurial treatment, as well as iodides, etc., were employed. A year ago the patient came under the writer's care, complaining of sacral and sciatic pains. Notwithstanding that these pains were not of the sharp, stabbing, shooting character usually described in locomotor ataxia, the patient was, on the strength of the history and in the absence of any other manifestations or signs, even after a most searching physical examination, put first on "mixed treatment," later on iodides alone, in doses increased to tolerance. No improvement taking place, the aforesaid specialist was again consulted, but, as he approved of the treatment, iodides were continued for over six months, when the patient went to the country for complete rest and absence of business cares. On returning to the city in September last the patient had a long tale of woe to relate. The sacrosciatic pains had improved somewhat during the preceding month, retardation in micturition, even at times retention, had taken place, and the greater part of the previous month had been spent in almost constant attention to the bladder. The rectum was also very sensitive with a constant feeling of distention and tenesmus. On examination the prostate was found considerably enlarged and the rectum, as well as the prostate, exquisitely tender. The urine showed bacteria and pus in abundance, and stained specimens (still in my collection) proved the presence of gonococci in the epithelial and pus cells. The urethra was so sensitive that the most gentle introduction of a No. 24 sound, although meeting no obstacle, was so painful that no more passing of sounds was considered advisable. Daily bladder-irrigations were given, at first with permanganate solution, later with boric acid, protargol and silver nitrate solutions. Urotropin in 7.5 grain doses was taken by mouth, b. i. d. Salol, hyoscyamus, alkaline diuretics, even methylene blue, as well as opium and other suppositories were resorted to. Notwithstanding, the urine gradually cleared up and sounds up to No. 32 were admitted, the difficulty in micturition still persisted, causing at times retention which necessitated midnight catheterizations, etc.

Although the diminished knee-jerk and other symptoms not for one moment allowed one to forget the possibility of tabes, operative interference was deemed advisable and a well-known, prominent surgeon performed external urethrotomy on October 25, 1899, which operation with its subsequent drainage and rest was considered as a possible cure. I regret to say that such did not prove the case, however, and although the vesical and urethral irritability disappeared, incontinence, especially nocturnal, set in. During the patient's convalescence from the operation the signs of tabes became gradually more pronounced, and the writer tabulated the following symptoms observed before consulting Dr. E. D. Fisher in conjunction with the surgeon in the case in the latter part of November. These symptoms are numbered in the order in which they appeared: (1) Sacral and sciatic pains. (2) Prostatic, rectal and bladder symptoms. (3) Decreased knee-jerk. (4) Strabismus. (5) Anesthesia and hyperesthesia in spots. (6) Argyll-Robertson pupils. (7) Slight Romberg symptom. (8) Ptosis of right eyelid with palsy of right internal rectus and some paralysis of the other ocular muscles of right side. (9) Inability to stand on one leg or walk a straight line with eyes closed. (10) Partial ataxia of hands and feet, as in touching things while eyes are closed. (11) Characteristic gait, weakness of legs and dizziness. Dr. Fisher examined the patient with great care and confirmed the diagnosis of locomotor ataxia.

The patient was again given inunctions of ung. hydrarg., and also increasing doses of iodide, together with Blaud's pills, arsenic, warm baths, rest in bed, etc. The nightly recurrence of incontinence, as well as frequent dribbling during the day, persisted, however, and caused the patient no end of discomfort. After various palliative measures had failed the writer decided, fin-

ally, to see what effect spermin would have. All other medication was consequently discontinued and 1 c.c. of Poehl's spermin was administered daily by hypodermic injection from January 11-23, 1900. After six injections the incontinence, bladder and rectal pains had disappeared altogether, the general tone, well-being and cheer improved considerably, the sexual appetite, which had been absent for months, returned, and the patient claimed to walk much better than before treatment commenced. The patient and his family were well pleased with the result obtained, but, as the ptosis and ocular motor symptoms still persisted, it was considered advisable to continue the spermin until twelve injections had been given. The general condition of the patient improved still more, the unpleasant hyperesthesia disappeared almost entirely, micturition became almost normal, and even the gait and unsteadiness improved considerably.

Case II.—Mr. Z. has suffered from paralysis agitans since 1889. Before coming under the writer's daily observation, some eighteen months ago, the patient was for several years treated by two of our most noted neurologists. The name, nature and prognosis of the disease are also perfectly familiar to the patient and his family. The general condition is very fair, thanks to a most careful regimen and good nursing, etc., made possible by the patient's circumstances.

During one of the temporary "bad spells" eight ampulla, each of 1 c.c. spermin, were given hypodermatically in as many consecutive days with very good results. Spermin seemed in this case to have a decided soporific effect. The frequent insomnia, which in this patient in almost every instance seems to be caused by autointoxication from gastro-intestinal disturbances, is usually relieved by a single injection, and the stumbling gait, which is always worse when the patient is upset, is also most gratefully affected. The patient, who is an exceptionally intellectual, bright and logical man and a keen observer, claims a very invigorating effect and added comfort. He says that spermin seems to relax the spasticity, which gives him rest, even although the tremor is not much affected, and he asks also for an occasional injection, whenever his usual equilibrium is upset.

A NEW METHOD FOR RETROPERITONEAL DRAINAGE OF PYOSALPINX, WITH A REPORT OF FIVE CASES.[1]

By LEON F. GARRIGUES, M.D.,
OF NEW YORK;
ATTENDING GYNECOLOGIST TO ST. MARK'S HOSPITAL; INSTRUCTOR IN SURGERY IN THE NEW YORK SCHOOL OF CLINICAL MEDICINE.

In presenting the subject of operations for pelvic suppurations, I am aware that I touch a subject over which many of the ablest minds in gynecology have disagreed since the beginning of the art, and it is only the fact that they have disagreed that emboldens me to add my quota to the discussion.

I need scarcely dwell on the disastrous results that follow the induction of the premature menopause through castration, although it is a topic that does not receive the careful consideration that it should. So many women suffer more from the nervous effects following removal of ovaries than they did from the disease for which these organs were removed. Therefore, in my opinion, salpingo-oophorectomy for purulent collections should never be done until vaginal drainage has been tried. This applies equally to hysterectomy whether the abdominal or vaginal incision, now becoming so popular, is practised. Vaginal drainage, if properly done, is scarcely dangerous to life. Even its opponents admit that a permanent cure follows it in the majority of cases, and that when this does not occur the patient is left in a better condition for a radical operation than she was previously.

Therefore, it seems logical to me that all pelvic suppurations should be drained by vagina, and, only in the event of failing to produce a cure, should a more dangerous operation be considered.

J. Veit, of Leyden,[1] lays down as indications for vaginal incision of a pyosalpinx, a high temperature, particularly if the patient is much prostrated, even if only as a primary procedure, as the patient's condition is much improved thereby, and the contents of the tube rendered less virulent. Therefore, he continues, vaginal incision is a good, if not always radical, procedure. He mentions as the cause of failures that only one part of a pyosalpinx is drained, and that hence the other part may keep up the infection. It seems to me that this objection is done away with by using a T-tube of large size with the upper part of the T long enough to drain the entire sac and allow injected antiseptic solutions to reach every part of it, and by allowing the tube to remain until nearly all discharge has ceased. Infections, other than gonorrheal, will then rapidly be cured, and even the latter by somewhat more prolonged treatment. Personally I have not had any recurrences in my own cases that I know of, or in those of other operators whose work I have observed, but I have seen in one case a fistula left that obstinately resisted treatment. As a rule, after vaginal incision of a pyosalpinx, the temperature promptly drops to normal, pain ceases, and there is no shock. In a week or less the patient is up and in from three to six weeks she is well.

Now let us look for a moment at the results of a laparotomy for pyosalpinx. There is often severe shock, and considerable pain lasting for long periods: the patient must remain in bed at least a month and it will, in many cases, take a year before she is really well and strong again. Frequently painful exudates form around the stump, which sometimes suppurate. There is considerable chance that later a ventral hernia will form, not to mention the fact that even in the hands of

[1] Read before the New York County Medical Association.

[1] Handbuch der Gynecologie, Vol. III., p. 800.

the best operators salpingo-oophorectomy for pyosalpinx entails a considerable mortality. It seems to me that the two pictures speak for themselves. Occasionally a case will not get well from vaginal incision alone, but are not our clinics and consulting-rooms full of patients who did not get well after laparotomy?

It seems to me irrational to ligate and excise a tube when the part left may contain virulent bacilli, which have now fine culture media in the shape of raw surfaces and serum, and no place to drain except into the peritoneal cavity. If the stump does contain virulent bacteria, the patient is not cured, and she may be worse off than she was before operation, as I have frequently seen to be the case.

Howard A. Kelly and others advocate puncturing purulent pelvic collections with a pair of sharp-pointed scissors, which are withdrawn open, and packing the cavity with iodoform-gauze. This technic is a faulty one, in my opinion, as I have seen hemorrhages follow the use of a sharp instrument in this way; in addition there is no guarantee in many cases that a loop of intestine will not be perforated. Gauze-packing is not only painful for the patient, but on account of the remarkable tendency the vaginal incision has to heal, the packing is compressed and therefore does not drain the cavity properly. Dr. Kelly reports excellent results, so far as cure and mortality are concerned; he states, however, that he has opened the free peritoneal cavity nine times in sixty-five vaginal incisions.

Now, as approximately one-half of all pyosalpinxes removed by operation contain virulent bacilli, it seems to the writer that the technic should be improved so as to obviate the dangers of contaminating the peritoneal cavity with septic material. Dr. Kelly, speaking of purulent pelvic collections not in contact with the vagina, advocates performing a laparotomy and pushing the pus-sac or sacs down into Douglas' cul-de-sac where they may be reached by vaginal puncture.

Landau[1] advocates vaginal incision of pyosalpinx if ever so small a portion of the sac is unmistakably in contact with the vagina. If after the incision, which he makes with a scalpel, he is in doubt whether the free peritoneal cavity has been opened, he unites the edge of the opened sac to the vagina by means of a number of hemostatic forceps, which he allows to remain *in situ* about forty-eight hours. He lost two cases from septic peritonitis in three hundred vaginal incisions. In the technic which I propose the peritoneal cavity is not opened, even if the pyosalpinx is at considerable distance from the vagina. This would make a preliminary laparotomy unnecessary in the class of cases referred to by Dr. Kelly, and would obviate the risk of contaminating the peritoneal cavity in the cases in which any doubt exists as to the sac being in contact with the vagina.

The technic for vaginal incision of pyosalpinx advocated by J. Veit is to make an incision over the most prominent part of the swelling, extending through the vaginal wall, and then dissecting bluntly with the forefinger toward the center of the mass until the hard resistance of the tubal wall is encountered, and then to perforate it with a trocar or pair of scissors, then inserting a drainage-tube through the opening. This, as far as I know, is the usual method employed, although several, not very important, modifications are in use.

The method answers very well if the sac is in contact with the vagina, or if enough exudate or adhesions exist to wall off the tube from the free peritoneal cavity; but in many cases, of which the five I have chosen are examples, this is not the case. Thus, if this method be followed in these cases the free peritoneal cavity is traversed and death may follow from septic peritonitis, if the germs in the pus are virulent. As a matter of fact, I have seen this occur several times, therefore I was led to think of some way of opening the tubes without entering the peritoneal cavity. The fact that the uterus is partly covered with peritoneum, and that the broad ligaments are composed of two layers which can be separated, gives us the possibility of draining pyosalpinx retroperitoneally, and all other purulent collections in the pelvis without entering the free peritoneal cavity. Of course, in the latter case the peritoneum must be perforated, unless the pus lies between the layers of the broad ligament, but this is an anatomical fact although not of clinical importance. Therefore, the technic here described need be only slightly modified if we have to deal with an ovarian abscess or localized purulent peritonitis.

The operation which I have performed in the following cases is done in this manner. An incision is made at the uterovaginal junction, beginning just behind a transverse line drawn through the cervix on the side corresponding to the pyosalpinx and carried backward, following the contour of the cervix for three-quarters of an inch. This incision is made close to the uterus and extends through the thickness of the vaginal wall. In making this incision the uterus is pulled down and the vagina made tense with bullet forceps. The left forefinger is now introduced through the incision, if the inflammation is on the right side, or the right forefinger if it is on the left. The forefinger is gradually pushed higher, keeping close to the side of the uterus, thus separating it from the cellular tissue. Next the junction of the posterior cul-de-sac and the uterus, close to the broad ligament, is reached: from now on it is important to use care in manipulating so as not to tear the peritoneum. It usually strips off readily from the uterus, but when the inflammation is of long standing this is not always the case. We continue stripping off the peritoneum until we reach the origin of the Fallopian tube. The upper portion of this opening should be between the uterus and the folds of the broad ligament and the space should be large enough to admit the index-finger

[1] Ueber Tubensache, Archiv für Gyn., Bd. XL., p. 85.

with some room to spare. The tube should be opened at this point if it is a prominent part of the sac. If, as is usually the case, the greatest bulge is more external, the finger separates the layers of the broad ligament until the most prominent point is reached. A pair of blunt forceps, curved on the flat, is now introduced with the other hand, and, while an assistant presses on the pyosalpinx from above, is pushed into the lumen of the tube under guidance of the index finger and opened, thus allowing the pus to escape.

This part of the operation must be done with great care and exactitude, so as not to open the free peritoneal cavity or perforate the pyosalpinx. The finger is now introduced through the opening in the sac and a thorough exploration made in order to be sure that no compartments are left undrained and that no ovarian abscess exists. Should the latter be present, the layers of the broad ligament should be still further separated and the abscess punctured. Having opened the tube and found no complication a rubber T-drainage tube of large size and good quality is introduced with a pair of forceps and allowed to remain.

The abscess is not irrigated at the time of operation lest a minute opening into the free peritoneal cavity might exist, and thus infectious matter be introduced into the peritoneal cavity. The vagina is now loosely packed and the tube cut short at the vulva. As a preliminary step all cases should be curetted. This insures a healthy endometrium.

Case I.—Mrs. C. had large pyosalpinx of left side, not in contact with the vagina. It was probably of gonorrheal origin as her husband had had a specific urethritis three years previously and her complaints began shortly after this date. She was operated on by the above-described retroperitoneal method and about ten ounces of pus were evacuated. The tube was removed in six weeks. She has remained perfectly well since her operation one year ago.

Case II.—Following a miscarriage the patient developed a left pyosalpinx not in contact with the vagina; she was operated on as above described. The tube was allowed to remain three and one-half weeks. She has had no trouble since.

Case III.—After dilatation of the os one year before operation, by another physician, patient has had trouble on the left side. When I saw her, three months ago, she had a large pyosalpinx of the left side not in contact with the vagina. Operation as above described. Tube was allowed to remain in four weeks. The patient has been perfectly well since.

Case IV.—The patient was sick one and a half years with a left pyosalpinx, probably of gonorrheal origin. She was operated on in July, 1899, and had no trouble until two weeks ago, since which time she complains of slight pains in the left pelvic region.[1] Vaginal examination did not reveal any abnormality, except some restriction of the mobility of the uterus, and some scar tissue at the site of the operation.

Case V.—Patient, thirty years of age, had pain in the pelvis for the past year and at times chills and fever. At long intervals pus was discharged through uterus. For several months she had almost constantly flowed, which together with a temperature, at times of 103° F., had necessitated her confinement in bed. She was very much exsanguinated and weak. Vaginal examination revealed a mass in the right broad ligament the size of a small fist and of stony hardness. High up in the pelvis on the left side a pyosalpinx could be felt. The uterus was absolutely immovable and somewhat enlarged. This case presented considerable difficulty. First, an incision through the vagina over the bulging mass to the right of the uterus was made and a blunt pair of forceps pushed into it and withdrawn open. The left pyosalpinx was drained retroperitoneally as described, but with considerable difficulty on account of the immobility of the uterus and the high position in the pelvis that the sac occupied. T tubes were inserted in both cavities and removed in four and five weeks respectively. The patient has been perfectly well since.

The last patient was in easy circumstances and had a trained nurse and every attention; the others were operated on in tenement-houses, and received only unskilled nursing. I do not regard it as necessary or even preferable to operate on these cases in a hospital, as the disinfection of the patients and hands of the operator and assistants and the boiling of instruments can be done equally well anywhere. Dressings, towels, sponges, etc., may be brought in a portable sterilizer.

To recapitulate: Retroperitoneal drainage is a comparatively safe operation. It is usually not very difficult of performance. It is reasonably sure to cure permanently. It leaves the generative organs *in situ*. Therefore, I advocate vaginal incision and drainage in all pelvic suppurations in contact with the vagina, and retroperitoneal drainage in all pelvic suppurations not in contact with the vagina.

Discussion.

Vaginal Route in Gynecology.—In the discussion Dr. J. Riddle Goffe said that he has been for a long time a persistent advocate of the vaginal route in the surgical treatment of pelvic diseases in women. No man is justified in his opinion in doing a laparotomy for any pelvic disease, no matter what it may be, if the affection does not extend above the brim of the pelvis, unless he has first tried what can be accomplished by the vaginal route. Dr. Garrigues' method is new. It seems ideal, however, rather than practical. It would certainly not be easy to do all the manipulation suggested by Dr. Garrigues without opening up the peritoneal cavity rather freely. A serious objection to Dr. Garrigues' method seems to be that, in the layers of the broad liga-

[1] These pains have since disappeared.

ment which he proposes to open up so freely, there is an important layer of cellular tissue containing a large number of important lymphatics. The pus from pyosalpinx and from abscesses of the ovaries may not be, and often is not, very virulent, but, on the other hand, it often is of extreme virulence. To allow this to drain over the large lymphatic spaces that would be opened up in the layers of the broad ligament, would be to invite danger not only of further spread of the disease locally, but even a certain danger of constitutional infection. The effort to save the peritoneum may result, then, in a general septicemia. In addition to this the operation suggested is too temporizing. The pelvic tissues are not exposed to view and the true character of the pathologic condition that exists is not definitely ascertained. Not more than one operation should be necessary for any case of pelvic disease, unless the patient is in extremis. It would seem preferable to open up Douglas' pouch freely, explore the conditions that exist thoroughly, and then do whatever is necessary to cure the patient, using the anterior vaginal incision through which to complete the operation.

The Anterior Operation.—Through an incision carried between the uterus and the bladder, the uterus and its adnexa may be turned down into the vagina and thoroughly examined. In order to deliver these organs it may be necessary to rupture abscesses. For this a large pad may be packed in and the peritoneum thoroughly protected. When the uterus and its adnexa are directly in view, conservative surgery of the highest order can be done without risk to the patient. This is the day of conservatism in gynecology. To leave even a small part of one ovary means that a woman will not suffer from the nerve-storms which characterize precocious menopause. In a number of cases recently in which only a minimal portion of one ovary could be left, menstruation continued uninterrupted and regular and no nervous symptoms developed.

Posterior Vaginal Operation.—Dr. Janvrin said that as Dr. Garrigues' procedure was new to him, he could say nothing definite about its possible advantages or disadvantages. The posterior vaginal route is his favorite operation and does not, to his mind, involve much danger. Free drainage by means of gauze or a good-sized drainage-tube will always relieve the peritoneum from any danger that it may be in because of the presence of infective agents in the pelvic suppurative processes. Dr. Goffe's objection to the danger of infecting the lymphatics of the broad ligament, if that structure is to be opened up, seems to be well taken. There is fully as much danger in this route as in the ordinary posterior vaginal route. As to the anterior operation, there is no doubt that in skilled hands it can be a very thorough and successful operation. The tissues may be thoroughly examined and the operation planned so as to remove whatever is considered to be diseased, saving all other tissue.

Dr. Boldt said that he does not think it possible to open a pyosalpinx high up by the method described by Dr. Garrigues. A suppurative process in the pelvis does not mean one abscess-cavity, but usually several. Purulent collections are sacculated and it is not sufficient to drain one of the sacs; all of them must be thoroughly emptied or the operation will have to be repeated. It is not as easy as it might seem to be, from the description given by the reader of the paper, to find the small Fallopian tube, and, when found, it is not always easy to open it, as its walls may be thickened and may be closely adherent to surrounding structures. Douglas' cul-de-sac should be widely opened. Often it will be advisable to make an opening large enough to admit the whole hand. It must be remembered that not all purulent processes are pus-tubes. There may be other pus collections in the pelvis and they should be carefully looked for.

Dr. Garrigues, in closing the discussion, said that the objection that his operation would open up the lymphatics between the layers of the broad ligament is well taken, but only theoretically. As a matter of fact, adhesions always form where the pus has collected for some time and the exudation has shut up the lymphatics so that they no longer absorb normally. In all of the cases operated on by this method, the temperature dropped promptly to normal, on the second to the fourth day after operation, and there were no further symptoms of the presence of pelvic suppuration. The patients were able to get up and be about in a week.

INAUGURAL ADDRESS.

By EDWARD D. FISHER, M.D.,
OF NEW YORK;
PRESIDENT OF THE AMERICAN NEUROLOGICAL ASSOCIATION.

GENTLEMEN:—Before bringing to your attention the principal subject of my remarks, as I open another annual meeting of our Association, I would take the opportunity to express my appreciation of the honor conferred on me by my election as President of the American Neurological Association, and especially at this time, when the Congress of American Physicians and Surgeons holds its triennial at Washington.

The position of neurology among the divisions of medicine and surgery has changed very much in the last twenty or twenty-five years. Perhaps no special branch of medicine comes into quite so close touch with general medicine and medical surgery as neurology. The work which has been done by many in our field in this country, those living and dead, has also established neurology on as high a level of honor and respect as any of the departments of medicine. This was not always so, as in our special field there has ever been an opportunity for the charlatan to exercise his talents.

The great progress in our knowledge of the anatomy and pathology of the nervous system, the acquirement of which knowledge calls upon

the highest kind of intellectual study, has had much to do with this.

In the old world, owing largely to the clinics held at the medical colleges, the reputation of the various teachers became world-wide. It is, however, only within the past quarter of a century, if so long, that the medical colleges with us have recognized the paramount necessity of a full and thorough course in psychiatry and neurology. This implies at present that in every well-organized college a previous thorough training in the minute anatomy of the nervous system has become necessary. Without this latter no proper instruction can be given in disease of the nervous sysem.

A very important point for us to consider, if we wish this high standing in the community to be maintained, is that we must not separate ourselves from general medicine. We must also study general disease. Other specialties may remain narrow and limited, but it should not be so with ours.

We are more often than others called as a sort of last resort to cases after many opinions have been expressed. Our diagnosis must be one often by exclusion. We must, therefore, be able to recognize, and, indeed, must fully understand, general diseases. We should be as able to examine the heart and lungs and other internal organs, and to recognize disease in them, as we are to make out disease of any special character in the nervous system itself. Again, a reason which also applies here is that these diseases of the general system may influence or cause the affections of the nervous system. A special illustration of this is seen in syphilis, which has such well-defined effects upon the nervous system. Some of the greatest names in neurology in Europe have always been connected with general medicine. I do not think it advisable to continue in general practice, at least to take care of any of the acute diseases, although some of the chronic diseases may often come under our care.

Another subject of importance for us to consider is that of therapeutics. We are too often, perhaps justly, accused of being more interested in the diagnosis and localization of a disease, and in the findings at autopsy, than in its cure. In calling us as consultants, however, the physician and patient are looking not only for a diagnosis from us, but also for some suggestion in regard to treatment. One of our most celebrated neurologists, Dr. S. Weir Mitchell, by his practical carrying out of a scheme or plan of treatment for nervous disorders which will always connect his name with the rest cure, has done much for the treatment of disease and also has spread the name of American neurology the world over.

I do not underrate the importance and necessity of the continued study of the histology and pathology of the nervous system. Our real advance is mostly due to this study and all our treatment has depended on such knowledge.

The note of warning I would now sound, and especially to those about to enter this field of medicine, is to keep up as broad a knowledge of all medicine as possible. No one should enter neurology as a specialty without having first had an experience in general practice.

I believe, if I read the signs of the times aright, that is the tendency of the neurology of the future.

Now we will enter upon the work of the session. We have an unusually full and excellent number of papers. Our Association has been successful and fortunate in its additions to its membership. We have now some most excellent candidates awaiting admission. It will be necessary to increase our membership, and from the attainments of those now applying I think it would be doing the Association a distinct injury not to so enlarge it. To continue to do good work we must ever be taking new blood into our Association.

Again thanking you for the high honor conferred upon me I declare this session now open for scientific work.

CLINICAL MEMORANDUM.

THREE CASES OF SUBCUTANEOUS CAPILLARY HEMORRHAGES IN EPILEPSY.

By CHARLES J. ALDRICH, M.D.,
OF CLEVELAND, OHIO;
LECTURER ON CLINICAL NEUROLOGY AND ANATOMY OF THE NERVOUS SYSTEM IN THE COLLEGE OF PHYSICIANS AND SURGEONS; VISITING PHYSICIAN AND NEUROLOGIST TO THE CLEVELAND GENERAL HOSPITAL AND DISPENSARY.

The occurrence of minute subcutaneous capillary hemorrhages during an attack of epilepsy has been recorded, but from the scant mention that literature makes of these occurrences the writer is convinced that the phenomenon must be extremely rare. The following cases are personal observations and are deemed worthy of record:

Case I.—F. L., aged forty-two years; bookbinder; married, and has one child, a boy fourteen years old, who also has developed epilepsy since his father began to have his attacks, one year ago. One year ago, in the middle of the night, his wife heard him making a peculiar noise and on going to his bed was unable to arouse him. She hurriedly dressed herself, but before she was ready to leave the house to call a physician he became conscious. There is no history of syphilis or hemophilia obtainable. He has been having these attacks of epilepsy about every two or three weeks, nearly all of them occurring in the night, the others occurring during preparation for bed, or just before rising in the morning. It was early noticed that after his epileptic attacks the chest, shoulders and neck were covered by red spots which upon examination were found to be minute subcutaneous capillary hemorrhages. The mild attacks were either unaccompanied by these hemorrhages or they were few in number, but a violent convulsion was invariably followed by these hemorrhages.

The following case was seen in consultation with Dr. Hicken and gave the following history:

Case II.—M. R., aged twenty-five years, railway clerk, unmarried. A few days preceding my visit and while in the office of Dr. Howard Straight he fell in a violent epileptic paroxysm. It was noticed that along the margin of both upper and lower lids of either eye was a bright red subcutaneous hemorrhage. Also beneath the ocular conjunctiva were several small hemorrhages. This was the second attack of epilepsy that he was known to have had. The other one presented like hemorrhages about the eyes and in the conjunctiva. In October, 1899, he underwent a slight surgical operation under chloroform anesthesia and it was noticed after the operation that he had hemorrhagic ecchymoses of the lids and conjunctiva. It was quite likely that while under the anesthetic he suffered his first epileptic paroxysm. This case is probably an epilepsy due to beginning multiple sclerosis.

The following case was seen in consultation with the late Dr. W. J. Scott and by him refered to me for treatment:

Case III.—S. E., aged thirty-four years; married; cigar-maker; no history of venereal disease or hemophilia. Has had epilepsy at wide intervals since fourteen years of age. He has had one interval of two years during which he had no attack. His seizures have always been of the major type and usually very violent. My first visit to him was the day succeeding a very violent attack. The upper part of the chest and contiguous areas of the neck were finely sprinkled with minute capilary hemorrhages, but never previously had his attention been called to them. I have observed him several times succeeding his attacks since that time and have invariably found a like condition to exist. There is nothing to indicate that he has any cardiac, vascular or blood disease that would especially conduce to the occurrence of these hemorrhages.

741 Prospect Street.

MEDICAL PROGRESS.

Intubation and Antitoxin.—It is now recognized throughout the world that intubation and antitoxin are the best methods of treating laryngeal diphtheria. Statistics of intubation without antitoxin show a mortality of 70 per cent.; with antitoxin, 30 per cent. The chief remedy advocated to diminish the mortality from this disease is the general adoption of a prophylactic dose of antitoxin to every child of croup-age, *viz.*, under ten years, exposed to diphtheria. The early use of a full dose is of greatest importance. B. R. Shurly (*Jour. Am. Med. Assoc.*, May 19, 1900) says that no case of laryngeal diphtheria should receive less than 1500 units and children over two years should have 2000 units, and an additional dose of 1000 units may be repeated every twelve hours according to symptoms. The more concentrated the serum, the more satisfactory for use. Additional medicinal treatment is of great value. The continuous inhalation of steam softens the laryngeal pseudomembrane. When the membranes are more adherent medicinal vapors from combined solutions of eucalyptus, oil of turpentine and carbolic acid are of value. Calomel vaporizations are of use in septic cases, as also are hourly doses of bichloride of mercury, gr. $^1/_{60}$ each. In considering the advisability of performing intubation, the following points are to be considered: (1) Stage of the disease. (2) Age of child. (3) Intelligence of parents. (4) Surroundings. (5) Trained nurse. (6) Amount of antitoxin and time when administered. (7) Distance of patient from operator. (8) Amount and character of dyspnea. (9) Complications. Urgent indications for operation are a small, frequent pulse, cyanosis, aphonia, and marked retraction of the chest-wall and epigastrium. In performing intubation particular attention should be paid to the position of the child and the selection of the tube. Ill-fitting tubes injure the larynx. No one should attempt the operation without having practised upon the cadaver, as an unskilful operator may endanger the child's life or injure the larynx and neighboring tissues. The removal of the tube is the most difficult part of the operation. This should be done, however, whenever the intubated child suffers from a recurrence of the dyspnea, as the tube may become occluded by food or membranes, or may be swallowed. The writer cites three cases illustrating some of the difficulties which the operator may meet. He also gives a summary of 100 cases operated upon, showing a mortality of 49 per cent. in children under three years of age, and of 19 per cent. in those over three years. He gives also the number of patients and the percentage of recoveries at each age. Shurly formulates the following conclusions and rules of procedure as applying to all cases of laryngeal diphtheria: (1) Administer antitoxin early without waiting for a bacteriologic diagnosis. (2) Tonsillar exudate attended by a croupy cough or partial aphonia is an indication for a full dose of 1500-2000 units of antitoxin. (3) Antitoxin administered twelve hours or more prior to operative interference will reduce the mortality of intubated cases at least 50 per cent. (4) Minimize all exposed children of croup-age. (5) Continuous steam inhalations are of great value in all cases. (6) Early operation is most strongly advocated.

Petrosulfol.—S. Ehrmann (*Wien. klin. Rundschau*, may 6, 1900) describes a new bituminous product resembling ichthyol and containing much sulphur called petrosulfol. This preparation may be used in ointment or watery solution. The class of cases best adapted for this remedy are the various eczemas, follicular, pustular, dry, and those with but slight exudation. The largely exudative type is not influenced by it. The eczema in which it has attained the very best results is that described by Unna as eczema keratoides. In

sycosis, also, good results are reported. The combinations most in use for these conditions are:

℞ Petrosulfol 4.00
Ung. casein .....20.00—40.00

℞ Petrosulfol 6.00
Lanolin .....
Vaselin aa..... ....20.00
Zinci Oxid. Amyli, aa 10.00

This second combination forms a rather stiff paste which may be applied by means of a gauze dressing to the eczematous parts. Petrosulfol does not in any way injure the clothing of the patient and disappears from it after a few washings. It causes furthermore no exacerbation to the acute forms of skin-diseases and no inflammatory reactions occur. The author has frequently used it in severe forms of sycosis by means of cataphoresis with good effect. In order to test the efficacy of petrosulfol theoretically, Ehrmann mixed it with pure gelatin cultures of staphylococcus pyogenes albus and aureus. Those cultures with weak solutions of petrosulfol increased only slightly in mass while those that had been treated with ten-per-cent. petrosulfol ceased growing entirely. These experiments tempted Erhmann to use petrosulfol in cases of furunculosis in cataplasms of ten-per-cent. strength, with the result that the induration became less marked and the inflammatory process receded quickly. In pernio simplex the preparation was used with collodion. Also in erysipelas, petrosulfol mixed with a weakened solution of Liquor Burrowi, good results were obtained. In the blennorrheic diseases petrosulfol has proven invaluable. After incision, periurethral abscesses dressed with it have healed completely within a short time. In suppositories this preparation was effective against blennorrheic prostatitis. Finally it may be said that untoward results following the use of petrosulfol have never been witnessed, no idiosyncrasy as yet having been found.

Malaria.—For the diagnosis of malarial fever, says A. Woldert (*Medicine*, May, 1900), a fresh specimen of blood is to be preferred. This is obtained by holding a cover-slip against the drop of blood without touching the skin, and then letting the cover-glass fall by its own weight upon a slide. If the blood does not spread quickly, or if it forms rouleaux, discard the specimen. The plasmodium has a turning, twisting, rotary, or flattening-out movement, and in the later stages contains fine pigment granules in active motion. The movements of the organism cease as the blood becomes cold. The tertian parasite is at first about one-fifteenth the size of a red blood-cell, is hyaline and devoid of pigment. It moves and is continually changing its contour, and it soon accumulates reddish or brownish pigment. An hour or two before the paroxysm it occupies the entire body of the red cell; then the pigment collects near the center, and at the time of the chill the organism splits into fifteen or twenty segments. Flagellated bodies are often seen. It is not until several hours after a paroxysm that the leucocytes contain pigment. The quartan parasite is slower in its movements, its pigment-granules are coarse and dark and collect near the periphery in a star-shaped manner, and it splits up into six or eight hyaline bodies. The estivo-autumnal parasite cannot be differentiated from the others in the early stages, but later it may enclose the red cell so that it looks like a ring, or may form a crescent with rounded ends and containing pigment; these latter, however, are seen only after the fever has persisted for several days. For staining the blood, make an even spread by drawing the edge of a slide bearing the drop of blood along the surface of another slide, dry in air, and fix by immersing in alcohol and ether for some minutes, or by exposing to a heat of 115°-120° C. for thirty minutes. Then apply one-half-per-cent. eosin solution in fifty-per-cent. alcohol for three to five minutes, wash in water and counterstain with saturated aqueous solution of methylene blue for five minutes.

Pathological Anatomy of Cancer of the Stomach.—According to B. Cuneo (*Revue de Chirurgie*, April 10, 1900) the local extension of gastric, especially of pyloric, cancer presents three very practically important features: The early and wide invasion of the submucosa; the tendency of the growth to travel toward the lesser curvature; and the usual integrity of the duodenum. The invasion of the submucosa follows that of the mucosa in a short time and rapidly exceeds its limits, owing to the loose structure and abundance of lymphatics in this layer. Indeed, often there are found aberrant extensions which are accounted for only by the early involvement of lymphatics just beyond the outlines of the proper neoplasm and an infection from these by contiguity of their submucous bed. The progression of the cancers of the pyloris toward the lesser curvature is remarkably frequent, having occurred in 9 of the 11 autopsies and in a preponderating majority of operative cases noted by the author. Its gross features, always substantiated by histological examination, are a white, pearly plaque, with hard round projections appearing to spring from the gastric wall. From this zone emerge cancerous prolongations downward over the gastric wall or upward into the lesser omentum, which is transformed into a sclerolipomatous mass, containing the blood-vessels and lymphatics. The anatomopathological researches demonstrate the confluence of the gastric lymphatic system along the lesser curvature and the violent and vast involvement of both trunks and nodes in the cancerous attack. Where the coronary blood-vessels leave the stomach the lymphatics usually do also, which accounts for a temporary arrest of the secondary deposits at this point and indicates the site for the incision in partial gastrectomies, namely, as

near the cardiac end as possible so as to remove the whole lesser curvature. While the duodenum so frequently remains intact as to make its entire escape the rule, nevertheless aberrant lymphatic deposits among the glands of Brunner and extensions by contiguity appear often enough to make resection of the duodenum for at least 2 or 3 cm. advisable. The study of the gastric lymphatic system leads to the recognition of three distinct groups, each with its definite clinical importance. First comes the coronary chain, comprising one group situate in the gastropancreatic peritoneal fold, and a second set along the lesser curvature proper, having a few scattered aberrant nodes about the cardiac end. Second is the hepatic chain which is of importance because to it belongs the right gastro-epiplotic series, consisting of a retropyloric and infrapyloric aggregation. Third, we have the splenic system, usually entirely discrete from that of the stomach. Since any or all of these, anatomically a part of the gastric system, may be early and severely infected, the indication is total ablation, because as soon as the first series of glands is degenerated general lymphatic involvement is assured and radical operation contraindicated. The removal of the lesser curvature with the entire coronary lymphatics appeared to be facilitated in the cadaver by the preliminary ligature of the coronary pedicle. The infrapyloric deposits are often so small as to escape attention. Therefore, the greater omentum must be divided widely and freely from the greater curvature, so as to include both the lymph-vessels and glands. In isolated cases these glands are anatomically incorporated in or adherent by inflammatory or cancerous deposits to the transverse mesocolon. Their removal, then, is exceedingly hazardous and often necessitates a resection of the colon. The extirpation of the retropyloric glands is always difficult because they are closely opposed to, and resemble the color and consistency of, the pancreas. They are also distributed along the gastroduodenal artery, from which severe hemorrhage may occur, so that its preliminary ligation at its origin may be an advisable procedure.

Treatment of Diabetes Mellitus.—It is a well-known fact that in spite of the many so-called specifics for the treatment of diabetes, there is still very little definite information in regard to the etiology of the disease, and no drug has yet satisfactorily relieved the condition unless combined with other methods of treatment, especially the dietetic. F. Kraus of Carlsbad (*Med. Rec.*, May 12, 1900) expresses the opinion that drugs have proven of little avail, opium being an exception but must be reserved for the very serious cases only. Hydrargyrum preparations seem to be of some value in rare cases of syphilitic glycosuria. The dietetic treatment, therefore, is the most efficacious and is sometimes curative, having for its object not simply to reduce the glycosuria but to keep the patient in the best form of nutrition. The best way of finding out the proper diet in individual cases is the following: The patient is put for one day on a limited amount of carbohydrates, say 100 grams of bread which contain about 60 grams of carbohydrates. Indifferent albuminous and fat products are also allowed. A twenty-four hours' specimen of urine is taken and the amount of sugar determined. If the glycosuria has not entirely disappeared, as in the mild cases, the carbohydrates are gradually increased until a trace of sugar is found and then we know what amount of carbohydrates the organism is able to assimilate, *i. e.*, "its tolerance for carbohydrates." This is the method used by v. Noorden in his clinic for diabetics. In cases in which the glycosuria persists a gradual reduction of carbohydrates is made until a diet as free from carbohydrates as possible is obtained. Great care must be observed in giving such strict diet and it can usually be followed only for a few days at a time. It must be interrupted if the patient is rapidly losing weight. In severe cases albuminous foods should be restricted as much as practicable, fats being substituted with vegetables containing very small percentages of carbohydrates. Periods of abstinence increase the assimilating force of the organism, and the continued use of carbohydrates diminishes the same. Therefore the patient should be told to include from time to time, at regular intervals, three or four days of strict diet, the intervals being chosen according to the severity of the case. Where glycosuria cannot be suppressed small amounts of carbohydrates should be allowed for albuminous material and fat alone will not meet the demands of the system for any length of time. Furthermore, it is superfluous cruelty to give some serious cases any sort of antidiabetic diet. It is always advisable to add the carbohydrates to the more copious meals, as dinner and supper, and the best way to give them is the form in which they have been accustomed to take them. The patient will usually prefer a small piece of plain bread to a larger piece of a surrogate. Alcohol may be used moderately and with careful selection. Balneotherapy has certainly been of considerable value in many cases and the effect is probably founded on the combination of many circumstances.

Mammary Cysts.—T. Bryant (*Lancet*, April 28, 1900), after analyzing some 230 cases of breast-tumor in his private records, announces these deductions: Simple mammary cysts are far more common than is generally believed; they are chiefly found in women at the same period of life as that in which cancer is found; they are mostly amenable to local treatment without sacrificing the gland; there is no reason to believe these women are more prone to cancer than others. With regard to the frequency of cyst-disease he states that out of every four cases more or less simulating cancer, one will prove to be a case of cyst-disease. By a free incision through the soft tissues the cyst may be emptied and dissected out. Where the cyst-wall is absolutely

free from anything like papillary or other growths it is sufficient to swab it out with carbolic acid or other caustic. When any growth, no matter how small, is found in the cyst-wall, excision is absolutely indicated, and when any intracystic growth is of a suspicious, fleshy, non-papillary nature, it is best to remove the entire gland. Of 68 cases treated by such conservative methods, every one has been permanently successful. Often serous occlusion-cysts, the size of a walnut, will disappear on improving the patient's general condition. In certain cases where the breast contains one cyst calling for interference, and also multiple small cysts, it is unnecessary as a rule to remove the entire gland, for with the removal of the large cyst the gland usually tends to return to its normal condition. Where the diagnosis is uncertain, as it must be many times, prompt exploratory incision is indicated.

Pelvic Peritonitis.—L. v. Luigen (*Med-Chir. Centralbl.*, April 6, 1900) recommends expectant treatment as far as possible in all cases of purulent pelvic peritonitis originating in the internal organs of generation. When such means have failed to restrict the progress or cure the condition and operative interference becomes necessary, he recommends in all cases vaginal drainage, irrigation and tamponade of the abscess. By digital palpation through the wound at the time of operation, the site, extent and complications of the disease can generally be determined and often drainage made more adequate than it would otherwise be. After the discharge is absent or at a minimum resort is then had to the usual local and systemic means to promote absorption of the exudate. Twenty-six cases are cited, showing how well this management results and how exceptional is the necessity of laparotomy for the disease. The one objection to it is that it takes longer to cure a patient by these means than by a laparotomy.

Plastic Covering of Defects in the Trachea.—H. Ane (*Arch. f. kl. Chr.*, Bd. 2, p. 125) considers that defects of the trachea usually originate in tracheotomies in early childhood. Their plastic relief aids not only the comfort of the patient but the development of the larynx. The use of tubes for many years often throws the larynx sufficiently out of function to hinder its growth to a remarkable degree. Suggestions have within a few years been made to cover such defects with bone-flaps. At the Twenty-second Congress of German Surgeons in Berlin, Schimmelbusch presented a 13-year-old patient with laryngeal stenosis and a defect of the trachea, two inches long, secondary to a tracheotomy for diphtheria during his second year. A flap of skin and bone was taken from the sternum, turned upward so that the skin presented inward. The raw outer surface of this flap was covered by skin taken from the adjoining lateral regions of the neck. The result was good. Again, at the Twenty-sixth Congress of the same body, F. König brought forward a seven-year-old child whose condition had been absence of the lower part of the larynx, especially of the cricoid cartilage, and of the adjoining trachea down to the manubrium sterni. The interval was filled with granulation and scar-tissue which formed the bed of the tracheotomy tube. This cicatrix was dissected away and the substernal tracheal stump freed and sewed posteriorly and as much as possible to the base of the larynx. Success followed the third effort for strong opposition. Later the absence of the anterior tracheal wall was supplied in part by the method of Schimmelbusch as above. A rather large sinus persisted. In a year this was closed by a skin- and bone-flap from the clavicle by a similar procedure. After four weeks the bone sloughed out, but the periosteum later supplied enough bone for rigidity. After two months the cannula was removed totally. The patient's breathing was natural, but he could only speak in a whisper. On the same occasion the younger König reviewed five other cases of laryngeal and tracheal defect treated by flaps of skin, periosteum and cartilage from the larynx, or the same with bone from the sternum. The case of the author was more difficult because of decided non-development of the larynx with deformity. The history was as follows: At two and one-half years of age boiling water was inhaled from a kettle-spout about six o'clock in the evening. At four o'clock the next morning a tracheotomy was done. Three months later he was still absolutely aphonic. Up to his eleventh year he wore the cannula without other attention. Physical examination on January 1, 1897, showed a strong fourteen-year-old boy, unable to breathe except with the tube. A scar extended from the presternal notch to the upper border of the thyroid cartilage with the tube-hole at the center. The hyoid bone was under size. The larynx small, in about the stage of development reached at the sixth year. The thyroid cartilage was deformed, probably by division at the original operation. The left half was the larger and overlapped the right. The true cords were paretic, inflamed, closely applied to, and hardly discernable from, the false, and separated slightly on phonation, which was hoarse and present only on respiration. The trachea was much stenosed, its rings were not distinguishable; its anterior wall was absent for about 5 rings, while posteriorly there was a mass of scar-tissue caused by the tube and involving most of the periphery. (This tumor promptly recurred after excision in May, 1894. Bougies were then tried. In April, 1895, excision was repeated and a transplantation of oval mucosa tried. In June, 1895, the same trial was repeated, while the cannula was omitted. In January, 1896, it had to be reinserted to avoid suffocation.) The rest of the physical condition of the patient was normal. The treatment was as follows: February, 1897, the scar-tissue causing stenosis of the trachea was removed and its site was covered by a lateral skin-flap, which united primarily. The greater difficulties of the laryngeal stenosis were overcome by the free use of

Schrötter's bougies which were passed from February 26th to May 5th, until No. 9 was admitted. Partial function of the voice was restored by using a tube with an upper opening. The use of the voice became less and less painful. The tube also prevented stenosis below by the flaccidity of the new skin-flaps over the area of the old cicatrix. In November, 1897, attention was given to the plastic restoration. The stenosis of the larynx was still such that breathing was severely dyspneic whenever the trachea was closed. Hence for almost a year apparatus was worn by which the patient was gradually helped and finally totally compelled to breathe through the normal passages. In October, 1898, Skliffossowsky did the operation as follows: A skin-flap was freed in its left and lower aspects and a bone-flap one-half its dimensions chiseled from the manubrium sterni. The excess of skin was folded and sewn over the bone, so as totally to inclose the same. Primary union resulted. Later the right border of the flap was freed and the whole opposed to the already freshened edges of the tracheal defect. The union was again primary. After the permanency of the union was certain, the pedicle of the flap was divided and separated. The sternal site of the flap was covered by portions of skin from the adjoining region and by Thiersch grafts. The cosmetic effect was good, the breathing and speech were much improved, and the restoration of the trachea was permanent.

Remarks on Pessaries.—Johannovsky (*Med.-Chir. Centralbl.*, April 13, 1900) says that, although modern gynecology seeks to correct permanently uterine displacements by operation, much can be accomplished by the pessary under suitable precautions, the first of which is antisepsis. Pessaries once used should always be sterilized by prolonged boiling; if the finish is injured they should be reburnished. The instrument must be surgically clean when introduced. Although the vagina carries this foreign body really well, full antisepsis is observed only by douching with weak antiseptic solutions once or twice daily. Again every three or four months a change of pessary is absolutely imperative. Choice of pessary is a matter of experiment in each case, best approached by first taking rather a small than a large one, as the latter are more difficult to retain and frequently cause discomfort and damage. Contraindications to their use are inherent in infectious vaginitis, acute and subacute inflammation of the uterus and its appendages. Respect for the periods of a woman's physiological life must be had. Virgins should be subjected to them only in extreme need, and the pregnant solely for the first three or four months, unless a simple prolapse of the vaginal walls is under treatment. Such patients wear them to term. None should be used earlier than the third week of the puerperium. During the climacteric the number and length of time should be gradually decreased owing to the process of involution. Hard rubber is the best material. As to the type of pessary the recommendations are as follows: The Hodge is the best of all, especially for mobile, reducible retroflexions. The Thomas, as originally designed, for a reserve instrument, when the former fails, usually in cases of marked relaxation and thickening of the posterior vaginal wall and of small freely-movable virgin uteri. The Mayer ring fulfils an indication in cases of descent with old pelvic peritonitis when the other types cause pain. Soft rubber may be used in this kind when the hard cannot be borne. The sieve or cup-pessary of Schatz supplants the former only when the weight it carries is small, as when the involution of the climacteric is complete, and in old virgins with atrophic organs. If too heavy it causes pressure-necrosis and is dangerous. Other mechanical means of uterine support are declared dangerous, and the use of the occluding pessary of Mensinger, for the prevention of conception, is allowable only for highest professional reasons.

Methylene Blue in Inoperable Cancer.—The *Therapeutic Gazette* (April 15, 1900) contains the report of a case of inoperable vaginal cancer by H. R. Coston. The vaginal examination disclosed a roughened and infiltrated area about one inch within the vulvovaginal orifice, and this surface extended around the entire canal up to and including the cervix and os uteri. The surface was very fragile and as a result of the examination, bled profusely. The left broad ligament and the inguinal glands were both enlarged and thickened. Although the patient's appetite was fair and the kidneys acting well, she was markedly cachectic. Operative measures were clearly out of the question. Coston began with local applications of methylene blue in the hope of relieving the patient from her most grievous symptoms. He used for the purpose a three-per-cent. solution in equal parts of alcohol and water, applying it every second day over the entire diseased area. The hemorrhage began to decrease from the first and the infiltrated area began to grow softer while the tissues became less fragile, permitting an ocular view of the os. Besides, tonics and alteratives were administered. Two months later, the hemorrhage had almost entirely disappeared, and the ulcerated surface had cicatrized, except in the left fornix. Four months after, there was frequently an entire week that elapsed without any pain being felt by the patient, when there would be a slight hemorrhage. The thickening of the broad ligament is, of course, increasing. The patient has, however, gained a few pounds in weight since treatment was begun. Coston does not claim any specific curative property for methylene blue and the patient, he says, will soon die from systemic infection. However, there is no doubt but that this remedy diminished greatly the chief annoyances of the patient, namely, hemorrhage and ulceration.

Phosphorus in Rickets.—An extensive literature is quoted by E. Kossowitz (*Therap. Monatshft.*, April, 1900) to support his view that with the introduction of phosphorus a new era in the treatment of rachitis has begun. Most authors are unanimous in the opinion that phosphorus aids the process of ossification, and that the convulsions, laryngospasm, insomnia and restlessness are better benefited by this than any other drug. The records of over a hundred thousand teach the author that phosphorus is the specific in rickets. He recommends it dissolved in cod-liver oil in which form it keeps well for months.

Clinical and Pathological Features of Ainhum.—A full and interesting account of this rare condition is given by J. Moreira (*Monatshft. f. prak. Dermatolog.*, April 15, 1900). Occurring most frequently on the Gold Coast of Africa and in Polynesia, it is found to a less extent in the larger cities of South America and the Southern States as well as in the West Indies. A shallow, circular constriction will first appear on the inner and under surfaces of the affected toe at the digitoplantar fold. As time progresses this groove will deepen until the toe remains connected with the foot by only a narrow pedicle. In the earlier stages neither pain nor inflammation is complained of, a slight pruritus and an increased mobility of the digit being the only subjective symptoms present. Later, however, the toe swells gradually and tenderness appears, and at the same time the edges of the sharply-cut furrow indurate and the base becomes ulcerous and covered with a fetid pus. Constitutional symptoms do not even now accompany this peculiar process and, other than the pain, the patients suffer but little inconvenience. Competent observers have classified ainhum as a manifestation of lepra mutilans, but the features of the two differ so much as to hardly demand serious controversy; for, while leprosy occurs among all races, shows no special predilection for the toes, and is an intractable, constitutional affection, ainhum involves only the fifth, more rarely the fourth, toe of negroes and can readily be cured if incipient by multiple incisions at right angles to the furrow. Then, also, gangrenous ulcers, pemphigus necrosis, atrophy and contractures, which are so often seen in leprosy, never occur. Pathologically a venous stasis, with subsequent edema and hypertrophy of the dermal layers, was found in the parts distal to the constriction; the latter itself showed a marked hypertrophy of the collagenous tissue of the skin. The author explains the occurrence of ainhum in negroes by their poor hygienic surroundings and the disposition to sclerosis inherent to this race, while the limitation of the disease to the two outer toes may be due to the greater obliquity of the fourth and fifth flexor tendons, owing to flatfoot. Trauma is an important etiological factor since those going barefooted are more often the sufferers. The disease runs a chronic course of from two to ten years, and has an excellent prognosis if early treated. Later, nothing but amputation will lead to cure.

Indications for Stimulation in Typhoid.—The four states to be combated by stimulants in typhoid fever are, according to J. H. Musser (*Therapeutic Gazette*, April 15, 1900), (1) toxemia; (2) exhaustion; (3) perforation, and (4) hemorrhage. Toxemia is recognized either by a state of ataxia or one of adynamia. In the former there are present excitement, erethism, active delirium, with cerebral congestion, flushed face, injected cornea, delusions, incoördination, twitchings, jactitations and restlessness. The pulse at first is full and strong. In this state cold applications are of the greatest use and alcoholic stimulation is to be avoided. The only drug of service here is opium. The coal-tar preparations are dangerous. Opium in small doses seems to have a stimulating effect and brings about relief in from twenty-four to forty-eight hours. Five or ten minims of the deodorized tincture every three or four hours has acted well. Adynamia is recognized by depression—exhaustion of the nervous, muscular and circulatory systems. This is the "typhoid state." Dulness, even stupor, low and muttering delirium, subsultus; apathy visible in the countenance; increased pulse, often dicrotic; diminished secretions, hot, dry skin, dry and brown tongue—all these are characteristic. Exhaustion is more profound each day. In this state stimulants are imperative, but should be used in small doses at long intervals. If the tongue becomes moist, the delirium lessens and a quiet sleep ensues after the alcohol. The kidneys also recover and the pulse slows and becomes stronger. Should the symptoms, however, become aggravated one must proceed very cautiously and employ stimulants other than alcoholic. The best guide as to the beneficent effects of stimulation is seen in the activity of the renal epithelium. If the urine keeps above fifty ounces per diem, plenty of water being used internally, no fear need arise. In old patients, with bad typhoid septicemia, champagne may be employed as well as spirits. Exhaustion is the result of the fever, the diarrhea, imperfect feeding, pathological discharges or abscess. Diarrhea must be controlled at almost any cost, for to this cause the greatest degree of weakness is due. Stimulation is here indicated in all quantities—from a few ounces of wine in twenty-four hours to many ounces of whiskey or pints of champagne. Perforation requires the same stimulation needed in surgical shock and it must be proceeded with gradually. In hemorrhage free stimulation is not "*en regle*," but gently and persistently adhered to, with opium, it gives good results. In convalescence, in order to overcome exhaustion and to aid digestion, stimulation must often be resorted to. This may vary from light wines or malt liquors to higher degrees of alcoholic beverages. Consideration must be had to the particular indications in each case.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

J. RIDDLE GOFFE, Ph.M., M.D., Editor,
No. 111 FIFTH AVENUE, NEW YORK.

Subscription Price, including postage in U. S. and Canada.

SATURDAY, MAY 26, 1900.

A NATIONAL THERAPEUTIC SOCIETY.

It is too often thought that the dreamer is a deep man; that the seeker after theoretical explanations of involved phenomena, because of his apparent lack of interest in things that touch gold, is above the suspicion of worldliness and is a model to pattern after. And it is to be regretted that in the minds of the student there should exist a certain small-souled contempt for the worker whose sole aim is the direct alleviation of bodily distress.

The man who practises medicine as an art has little time for so-called scientific work, and the man who studies medicine as a science seldom practises. Thus, the two sides of medicine are as completely opposed to each other as the reverse and the obverse of a coin; but together they make the currency of progress. There are few successful physicians to-day who do not appreciate how great a debt is due to the laboratory-working members of the fraternity; few, indeed, who could not themselves work up with the keenest appreciation, pathologic and bacteriologic questions involved in their most obscure cases; but life is not long enough. While they are puttering away over badly-smelling specimens, the flame of life goes out.

It is to the every-day worker among the sick that the world must look for improved methods of treatment and it is a sign of distinct progress that an idea was put into tangible form at the last Congress, which should have matured long before. That there is place for a distinct society whose object shall be to exemplify the end and aim of practical medicine, namely Therapeutics, needs no thesis.

A National Therapeutic Society with a platform of the ways and means of *treating* disease was inaugurated at Washington and we look for a large and active membership in so eminently suitable a project.

THE NEURONE CONCEPT.

Nerve-cells and nerve-fibers were the terms employed in the description of the structural element of the nervous system up to within comparatively recent years, but, more particularly, Italian, Spanish and German workers, have brought into general line the structure of the nervous system and have extended the biologic cell doctrine to this involved maze of elements. Apart from the many collateral and intricate questions of detail the neurone doctrine simply posits the cellular character of the nerve-unit. In the recent discussion of the neurone doctrine, held before the American Neurological Association, L. F. Barker outlined very clearly the biologic import of the doctrine and showed that, notwithstanding the many irregularities in technic and the manifest differences of interpretation of such technical modes of investigation, the neurone doctrine is fundamental and has come to stay, for some time at least.

Whether, as claimed by recent observers, the neurones are in actual physical contiguity or not, is an irrelevant question, if the fundamental biologic idea is kept in mind. Some contact of the individual units must exist, physiologically at least, and the question of their communication by fibrils, as apparently demonstrated by Apathy, has little bearing on the general concept.

The pathological data were very ably presented by Dr. W. G. Spiller and seemed to demonstrate, notwithstanding many anomalies, the general truths of the doctrine.

As outlined by Dr. B. Sachs, the doctrine has not helped very materially in the treatment of nervous affections. This, however, is not the fault of the doctrine, nor does it militate in any

way against its foundation in fact, but serves to bring out the extreme difficulties to be overcome in the treatment of so highly complex a tissue as that of the nervous system. The doctrine certainly may point out useful lines of treatment as its details are more thoroughly mastered.

RADICAL CURE OF INTESTINAL CANCER.

Next to the fact that cancer is on the increase, the most interesting advance in our knowledge of malignant disease from recent observations is that cancer of the intestine is occurring in younger subjects than it formerly did. Cancer specialists in such widely separated countries as France, Germany, England and America agree in this opinion. An offset to discouraging observation is the fact that operation for intestinal cancer is now neither so dangerous nor so hopeless as it once appeared to be. Excision of even considerable lengths of intestine has now been done so frequently and with such excellent results that this field of surgery is being exploited with comparative impunity. Confident skill in the technic of intestinal resection and anastomosis is expected, in our time, of every surgeon who seriously takes up abdominal surgery.

Undoubtedly the mortality from cancer of the intestines will be notably reduced as soon as the skill necessary for early and accurate diagnosis is developed among those who see such cases early in their career. The most characteristic symptom of growth of an intestinal neoplasm is the occurrence in patients with a history of chronic constipation, of attacks of acute abdominal distress that simulate more or less closely intestinal obstruction. In such cases careful abdominal palpation will often reveal the presence of a tumor. This is usually not large, but is apt to be very hard and somewhat nodular in character. The favorite locations are the flexures of the colon, especially the sigmoid, and the caput coli in the neighborhood of the ileocecal valve. Cancer of the rectum gives special characteristic symptoms that are not difficult of recognition while cancer of the duodenum can scarcely be differentiated with any accuracy from cancer of the pylorus.

The contraindications to operation for malignant disease of the intestine are few. The size of a tumor alone is never a contraindication unless there are other prohibitive reasons. The presence of adhesions is a contraindication only when they involve large blood-vessels or the bony skeleton or when they are due to cancerous infiltration. Inflammatory adhesions, due to the recurring attacks of localized peritonitis during the periods of incomplete intestinal obstruction, may bind down an intestinal tumor so firmly as to make it absolutely immovable, at least to external palpation, yet the adhesions may be readily broken up after laparotomy. Resections of such important organs as the liver and the pancreas may be successfully accomplished even where the infiltration is malignant in character, provided it is not too extensive.

While waiting for the solution of the problem of the etiology of cancer and of methods of treatment other than radical surgical intervention, the hope of reducing the mortality from malignant disease lies in early diagnosis of the presence of the cancerous tumor. In the breast and in the uterus there has been during late years a distinct advance in the line of early detection of the neoplasm. The diagnostic difficulties are greater in the case of cancer of the intestine, but the arrangement of the lymphatics of the gut is such that the extension of the cancerous process beyond its original ring of invasion is slow. The chances for radical cure are consequently greater at every corresponding stage of advancement. Many lives may be saved by keeping alive an active suspicion of anomalous symptoms of constipation in the middle-aged, and by insistence on careful examination of the abdomen when they exist.

ECHOES AND NEWS.

NEW YORK.

Hospital Benefactions.—By the will of Robert Schell the Presbyterian Hospital receives $20,000 and New York Eye and Ear Infirmary $5,000.

Death from Chloral.—Dr. Charles Smith Collins, living at 2183 Broadway, died May 20th from the effects of an overdose of chloral taken to relieve pain and induce sleep.

Addition to Eye and Ear Hospital.—A two-story addition is about to be erected in the rear of the present buildings by the New York Eye and Ear Hospital. The new structure will cost about $35,000.

Bellevue Appointment.—Dr. John B. Walker has been appointed Visiting Surgeon to Bellevue in the Third Division, College of Physicians and Surgeons.

The Polyclinic.—At a recent meeting of the Faculty Drs. Robert C. Myles and Francis J. Quinlan were appointed Professors in the Department of Laryngology and Rhinology.

New York County Medical Association.—The following officers have been nominated to be voted for at the next stated meeting: For president, Parker Syms and John Blake White; first vice-president, J. Riddle Goffe; second vice-president, Emil Mayer and Carl Beck; recording secretary, Ogden C. Ludlow; corresponding secretary, J. W. Draper Maury and R. Abrahams; treasurer, Charles E. Dennison and Charles I. Robyn; member of executive committee, Frederick Holme Wiggin.

Contagious Diseases.—For the week ending May 19, 1900: Measles, 618 cases, 23 deaths; diphtheria, 251 cases, 45 deaths; laryngeal diphtheria (croup), 13 cases, 9 deaths; scarlet fever, 154 cases, 16 deaths; smallpox, 2 cases, 1 death; chicken-pox, 12 cases; tuberculosis, 207 cases, 171 deaths; typhoid fever, 17 cases, 4 deaths; cerebrospinal meningitis, 4 deaths; totals, 1274 cases, 273 deaths.

Nurses for the Insane.—At the third annual graduation exercises of the Training School for Nurses, which is part of the Manhattan State Hospital on Ward's Island, forty-five nurses received diplomas. Most of these are women, and all of them intend to nurse the insane.

Testimonial to Dr. Jacobi.—The Woman's Health Protective Association, assembled at the Academy of Medicine on May 16th, adopted congratulatory resolutions and presented to Dr. Jacobi a testimonial, calling attention to his services in behalf of the Association. Dr. Jacobi, in reply, praised the Association for its achievements.

Christian Scientists and the Elephant.—There seems to be no limit to the ambition of the disciples of Eddyism. The latest stroke of advertising consists in making application to the Superintendent of the Central Park Zoo to treat "Old Tom," the elephant who has recently been indisposed. When told that they would not be safe for a moment in the cage with Old Tom they insisted that that made no difference, they could cure him at their homes, remarking that they often have patients as far away as China. Whether these patients are elephants appeareth not. As the elephant was already convalescent, we may hope soon to hear from the scientists that they have effected a complete cure.

Trinity Hospital Closed.—Trinity Hospital in Varick Street, which is controlled by Trinity Corporation, was closed May 15th for the first time since its foundation twenty-seven years ago. Extensive alterations in the building will be made during the summer. The hospital will reopen October 15th in charge of trained nurses instead of the Anglican Sisters of St. Mary, who have been in charge of it since its inception.

St. John's May Withdraw.—The authorities of St. John's Hospital, Brooklyn, are considering the advisability of taking that institution out of the list of city hospitals. It has been found that the money received from the City does not cover the expense of caring for the city inmates of the hospital, and it is believed that a saving can be made by conducting the hospital as a purely private institution. The parsimony of the City Government, which has cut down the pay for city patients to one-half what it costs the hospital, is condemned.

Brooklyn Doctors' New Home.—The new home of the Medical Society of the County of Kings, in Grant Square, Brooklyn, was dedicated on May 18th with appropriate ceremonies. Dr. Lewis S. Pilcher, President of the Society, presided, and the exercises included addresses by Dr. George M. Gould of Philadelphia, Dr. James H. Chadwick, Librarian of the Boston Medical Library, and Dr. Abraham Jacobi, Chairman of the Board of Trustees of the New York Academy of Medicine. The benediction with which the exercises closed was delivered by the Rev. John P. Chadwick, U. S. N., who was chaplain of the "Maine" and is now attached to the Brooklyn Navy Yard.

In Memory of Dr. Hammond.—The Post-Graduate Medical School held a Memorial Meeting on February 23d in honor of the late Surgeon-General William A. Hammond, who had been one of the founders of the school. The exercises furnished a monument more lasting than brass, and was a most appropriate tribute to the memory of the man. A full account of the exercises appears in the May issue of the *Post-Graduate*. Dr. Roosa recounted many interesting personal anecdotes and pictured the character of Dr. Hammond as a man; Dr. Joseph Collins spoke of Hammond, the physician and neurologist: Dr. Charles L. Dana of Hammond, the teacher; Dr. Joseph R. Smith, U. S. A., of Hammond, the Surgeon-General, and E. A. Lancaster of Hammond, the litterateur; Dr. Andrew H. Smith spoke of Hammond's professional career, and A. E. Lancaster presented a short poem. In thus honoring the memory of a colleague the Post-Graduate Medical School reflects credit upon itself, and we hope has established a precedent for similar institutions.

Hebrew Sanitarium Report.—In the twenty-second annual report of the Sanitarium for Hebrew Children, which has just been issued, it is stated that during the year 1899, 6090 day-patients were taken on excursions, 1546 were women and 4544 were children. Nine hundred and eighty-nine persons were admitted as weekly-patients to the institution at Rockaway Park. In addition to this number there were 8474 day-patients, of whom 474 were mothers. The receipts for the year were $44,830.63. The purpose of the institution is not to relieve want, but rather to build up the constitution of weak children, and to enable them to become healthy and self-supporting men and women.

PHILADELPHIA.

Polyclinic Staff.—The Philadelphia Polyclinic and College for Graduates in Medicine has recently elected Dr. James Thorington Professor of Ophthalmology.

St. Timothy's Hospital.—The heirs of Percival Roberts have donated $50,000 for a memorial addition to this hospital. The new building will be 140 by 50 feet in size.

Hahnemann Commencement.—The fifty-second annual commencement of Hahnemann Medical College was held May 17th, 58 men receiving diplomas. The address was delivered by President Patton of Princeton University. He deprecates the present tendency to specialization in medicine.

Medico-Chirurgical Commencement.—The annual commencement of the Medico-Chirurgical College was held May 19th, the orator of the occasion being President G. E. Reed of Dickinson College. In the medical department 37 graduates received diplomas. In addition there were 22 graduates in dentistry and 16 in pharmacy.

Health Report.—Deaths for the week ending May 19th were 535, an increase of 41 over those of the previous week and of 152 over the corresponding week of last year. Contagious diseases: Diphtheria, 82 cases, 33 deaths; scarlet fever, 60 cases, 12 deaths; typhoid fever, 75 cases, 9 deaths.

Weltmerism.—This so-called method of healing by magnetic influence is the latest "ism" to seek the sanction of the law in Pennsylvania. One of its adherents considers that the law does not prohibit its practice because no drugs are used. The Medical Council is kept busy defining who may and who may not practise the art of healing. And still new methods multiply.

College of Physicians.—The Section on Laryngology and Otology met May 16th. Dr. W. S. Hoch presented a case of mycosis of the faucial and lingual tonsils. The disease was of three months duration, the patient being otherwise in good health. Dr. Donnellan stated that some cases had been greatly benefited by tobacco-smoking. Dr. C. H. Burnett reported a case of acute otitic facial paralysis. He favors giving a reasonable time for nature to take care of the sequestrum where there is reason to believe dead bone is present. This is preferable to early operation. Dr. Bliss reported a case of operation for nasopharyngeal adenoids and deflected septum in a hemophiliac. It is his rule to inquire carefully whether there is a tendency to bleeding before operation, but this had been overlooked in the case cited. Hemorrhage was readily controlled at the time of operating, but began the next morning and was so severe for two days that the patient died four days after the operation, although the hemorrhage seemed to be under control for the last two days. He believes that laryngological and aural operations should not be done in cases where the history points to hemophilia, unless in exceptional cases of great emergency. A point emphasized in the discussion was that the hemorrhage in such cases does not immediately follow the operation, but begins from a few to twenty-four hours afterward.

The Section on Gynecology.—At a meeting held on May 17th, Dr. Beyea reported a case of papillary cyst of both ovaries with a recurrence in the posterior wall of the vagina some time after removal. This growth was encapsulated and was enucleated. Transference was believed to have taken place by the lymph-channels, but as this would be contrary to the flow of the lymph-stream the exact manner was not understood. Dr. Dorland read a paper upon the rôle of the liver in the production of eclampsia. He believes that there are certain cases of hepatotoxicity. This affords an explanation of fulminant cases where there is no albumin in the urine. Acetone is probably one agent concerned in this toxemia and the urine should be constantly examined for this substance. Dr. Krusen stated that cases of eclampsia were lessened in proportion as more salines and calomel were used in the later stages of pregnancy. This would point to the liver as being of some influence in the causation of eclampsia. Dr. Coles believes that the kidneys are not at fault in some of the worst cases of eclampsia and thinks the liver plays a large part in the cause. In one case of toxemia the patient was on the verge of eclampsia and yet there were no urinary symptoms. He does not pay much attention to albumin as a diagnostic point and thinks that cases will be treated better if more attention is paid to the amount of urine and the total solids passed. The renal form of elampsia is of more favorable prognosis than is the form which appears to be a toxemia from the liver. Unless kidney-disease is very bad it is not looked upon as unfavorable. One case of acute Bright's disease had one eclamptic convulsion and finally recovered. Dr. Coles gives calomel to toxemic cases, one-fourth grain three times a day, this giving better results than diuretics. This amount has been given continuously during the last two months of pregnancy with positive beneficial results.

CHICAGO.

The New Willard Hospital.—The new Frances E. Willard National Temperance Hospital was recently opened. It affords accommodation for about thirty patients at present.

Preservatives for Milk.—Health Commissioner Reynolds has declared that the use of preservatives to keep milk from souring is a direct menace to infant-life of Chicago. Restaurant men and caterers have declared the present milk-supply unfit for animals. Active measures will be taken by the Health Department to put a stop to the practice, and the names of dealers who violate the mandate of Commissioner Reynolds will be made public. Some dealers have already come under the ban of the Department. The

Commissioner has notified four firms manufacturing various preparations which they term preservatives, that such solutions are injurious and should not be sold. Offenders will be prosecuted under the City Ordinance which prohibits the adulteration of milk or the use of preservatives.

Officers of Illinois State Medical Society.—At the annual meeting, held May 15, 16 and 17, 1900, at Springfield, the following officers were elected for the ensuing year: President, Dr. George N. Kreider, Springfield; first vice-president, Dr. Weller Van Hook, Chicago; second vice-president, Dr. Denslow Lewis, Chicago; assistant secretary, Dr. O. B. Will, Peoria; treasurer, Dr. E. J. Brown, Decatur; permanent secretary, Dr. E. W. Weis, Ottawa. Section One—Chairman, Dr. Charles D. Center, Quincy; secretary, Dr. G. W. Nesbitt, Sycamore. Section Two—Chairman, Dr. M. L. Harris, Chicago; secretary, Dr. W. F. Grinstead, Cairo. Section Three—Chairman, Dr. Frank P. Norbury, Jacksonville; secretary, Dr. C. C. Carter, Rock Island. Peoria was selected as the place for holding the next annual meeting, May 21, 22, and 23, 1901. Chairman of the Committee of Arrangements, Dr. J. D. Henry, Peoria.

Public Health Matters.—There were 527 deaths reported during the week ended May 12th, an excess of 39 over the preceding week and of 24 over the corresponding period of 1899. The weekly bulletin of the Health Department shows that chronic diseases are chiefly responsible for the relatively high mortality, and of the acute diseases pneumonia is somewhat, and typhoid fever largely, in excess of the preceding week. Of the chronic diseases showing an increased mortality may be noted Bright's disease, heart-diseases, nervous diseases, cancer and consumption. There were 15 deaths from measles during the week, the greatest number reported for any week since the weekly mortality records have been kept. The great majority of these cases were complicated with pneumonia. The marked increase of typhoid-fever mortality should be a warning against the use of untreated hydrant-water by the young and non-immune. It is to be feared that the greatly improved appearance of the river since the opening of the Drainage Channel is misleading the public into the belief that our drinking-water is correspondingly improved, and that there is no longer any necessity for caution in its use. As much sewage is still poured into the lake as before the channel was opened; this will continue until the intercepting sewers are completed and the lake will be subject to occasional pollution, the effects of which will be shown in an increase of deaths from the acute intestinal diseases and from typhoid fever.

GENERAL.

To Study Yellow Fever.—It is reported that the Liverpool School of Tropical Disease is about to dispatch an expedition to South America for the purpose of investigating the cause of yellow fever.

The International Medical Congress.—It is officially announced that during the week of the International Medical Congress at Paris, August 2-9, free admission to the Exposition will be granted to members of the Congress. To secure this members will receive a special card by applying at the office of the Congress, 21 rue de l'Ecole de Médicine.

American Proctologic Society.—The following officers were elected at the meeting of this Society held at Washington, May 5, 1900: President, J. P. Tuttle, New York; vice-president, T. C. Martin, Cleveland; secretary, W. H. Beach, Pittsburg; members of the executive council, S. T. Earle, Jr., Baltimore, A. B. Cooke, Nashville, and J. R. Pennington, Chicago.

Cholera Kills Thousands.—A special despatch from Hyderabad on May 18th stated that more than forty-five famine camps have been attacked by cholera. At Gujerat many thousands have perished. In the Godhra camp alone there have been thousands of victims.

Vaccination by Force.—The alarming spread of smallpox in the State of South Carolina induced the Governor recently to issue public notices to all magistrates instructing them that they must issue warrants on the affidavits of health officers, and have persons, charged with refusing vaccination, arrested. Acting on this, the magistrates of the village of Union arrested men and women and took them to jail, where they were forcibly vaccinated by order of the town board.

Long Skirts and Disease.—The opinion is gaining ground in the profession that the continued prevalence of grip is due very largely to the germs being carried into the houses by the trailing skirts of women. Already it has been recognized that the dried sputum of tuberculous patients is being carried into homes and disseminated in the same way. Reform in this matter must come from the intelligent classes in every community. A few women of recognized social position could easily set the stamp of fashion upon the hygienic short walking-skirt.

The American Medical Association.—The proximity of Atlantic City, the place of meeting this year of the American Medical Association, will enable the members to visit both New York and Philadelphia before or after the meeting and look into the various clinics, medical and surgical. At Philadelphia a bureau of information for the benefit of members of the Association has been established at the College of Physicians, on the corner of Thirteenth and Locust Streets. Full information will be furnished regarding the situation of the various hospitals, medical colleges, etc., and the hours and dates of operations and clinics.

Barnard Medal for Roentgen.—The National

Academy of Sciences of the United States has recommended to the Trustees of Columbia University that the Barnard medal for meritorious service to science be awarded to Prof. Wilhelm Conrad Röntgen of the University of Würzburg for his discovery of the X-ray. The award will accordingly be made at the university commencement to be held on June 13th. This medal is awarded every quinquennial period "to such person, if any, whether a citizen of the United States or any other country, as shall within the five years next preceding have made such discovery in physical or astronomical science to purposes beneficial to the human race as in the judgment of the National Academy of Sciences of the United States shall be esteemed most worthy of such honor."

A Temperature of 119° F.—Dr. Frank Sampson of Penn Yan, N. Y., who is attending Lieut. Mary Gregory of the Salvation Army, reports continued high temperature in her case. She is twenty-four years of age, and has been suffering from appendicitis. On March 24th the temperature arose from 103° to 108° F. The next morning 112° F. was reached, the highest the doctor's instrument could record. A colleague was called in whose thermometer recorded the same degree. Four physicians and seven different thermometers were used and all recorded practically the same result. The degree of 112° F. was reached every day up to May 20th, fifty-five days in all, and a severe chill usually preceded the fever. The pulse was generally not over 120, and the tongue has been clean and the mind clear except when opiates were used. Once a thermometer registering 120° F. was employed, and with this Miss Gregory exhibited a temperature of 119° F.

The Plague.—Recent reports from San Francisco announce that an organization of Chinamen called "the highbinders" and the Board of Health have had a clash over the bubonic-plague question. By threats to assassinate any Chinaman who submits to inoculation against the plague, the former have prevented the Chinese from taking treatment. There are 23,000 Chinese in Chinatown, and they are terrorized at the prospect of vaccination with the Haffkine prophylactic. Surgeon General Wyman of the Marine Hospital Service insists upon the absolute necessity of having every Chinese inoculated. Surgeon Kinyoun, who has charge of the Federal sanitary interests in the State of California, is working in harmony with the State and local boards of health. To prevent the departure of Asiatics by means of the railroads crossing the State line, sanitary inspectors have been stationed at various points on the railways. Up to the present time there have been eight cases of the plague in San Francisco. All the victims died. Recent developments are awaited, although no new cases have been discovered up to May 23d. It was officially announced May 22d that several cases of the plague have been discovered at Rio de Janeiro. On May 21st the first death of a white man from bubonic plague occurred at Manila. The victim was a Government teamster. Advices from Honolulu up to May 15th declare that there had been no case of bubonic plague at that port for forty-six days, and business had resumed its former activity.

SPECIAL ARTICLES.

PRESIDENT ELIOT OF HARVARD AND ANTIVIVISECTION.

The Puritanical spirit is far from being dead and the fanaticism that burned harmless old women to gratify an Idea still stalks abroad in the land under the guise of philanthropy and love for the brute creation.

Self-righteousness and the ascetic ideal are frequently synonymous terms and when turned in the channel of antivivisection produce some very incongruous results. The first Gallinger Antivivisection Bill was one of these and, we rejoice to say, its bubble was pricked by a discerning Senate. But self-gratification is as proverbial in its spirit as the blood of the martyrs and a second bill, No. 34, having much the same import as the Gallinger bill, has been introduced in the Senate. With reference to this new bill, the enclosed letter of President Eliot of Harvard College is worthy of serious attention. It is here presented in full.

Harvard University,
Cambridge, March 19, 1900.

Dear Sir: I observe that a new bill on the subject of vivisection has been introduced into the Senate, Bill No. 34. This bill is a slight improvement on its predecessor; but is still very objectionable. I beg leave to state very briefly the objection to all such legislation.

1. To interfere with or retard the progress of medical discovery is an inhuman thing. Within fifteen years medical research has made rapid progress almost exclusively through the use of the lower animals, and what such research has done for the diagnosis and treatment of diphtheria it can probably do in time for tuberculosis, erysipelas, cerebrospinal meningitis, and cancer—to name only four horrible scourges of mankind which are known to be of germ origin.

2. The human race makes use of animals without the smallest compunction as articles of food and as laborers. It kills them, confines them, gelds them, and interferes in all manner of ways with their natural lives. The liberty we take with the animal creation in using utterly insignificant members of them for scientific researches is infinitesimal compared with the other liberties we take with animals, and it is that use of animals from which the human race has most to hope.

3. The few medical investigators cannot probably be supervised or inspected or controlled by any of the ordinary processes of Government supervision. Neither can they properly be licensed, because there is no competent supervising or

licensing body. The Government may properly license a plumber, because it can provide the proper examination boards for plumbers; it can properly license young men to practise medicine, because it can provide the proper examination boards for that profession and these boards can testify to the fitness of candidates; but the Government cannot provide any board of officials competent to testify to the fitness of the medical investigator.

4. The advocates of antivivisection laws consider themselves more humane and merciful than the opponents of such laws. To my thinking these unthinking advocates are really cruel to their own race. How many cats, or guinea-pigs would you or I sacrifice to save the life of our child, or to win the chance of saving the life of our child? The diphtheria antitoxin has already saved the lives of many thousands of human beings, yet it is produced through a moderate amount of inconvenience and suffering inflicted on horses and through the sacrifice of a moderate number of guinea-pigs. Who are the merciful people—the few physicians who superintend the making of the antitoxin and make sure of its quality, or the people who cry out against the infliction of any suffering on animals on behalf of mankind?

It is, of course, possible to legislate against an improper use of vivisection. For instance, it should not be allowed in secondary schools, or before college-classes for purposes of demonstration only; but any attempt to interfere with the necessary processes of medical investigation is, in my judgment, in the highest degree inexpedient, and is fundamentally inhuman.

Very truly yours,

C. W. Eliot.

Hon. James McMillan.

In strong contrast with this temperate and careful presentation of the main central features concerning the broader lines of vivisection, we note a lengthy article in the Baltimore *Sun* of April 16, 1900, which purports to be an interview with Senator Gallinger. If it were not for the deplorable fact that "copy" is worth so much a column, it would seem incomprehensible that so much balderdash could be dished up to what we must infer to be reputable citizens in one of the most enlightened cities of the East, almost under the shadow of one of our grandest institutions of learning.

Some of the more striking misstatements of the article in question have been very ably answered by Dr. W. W. Keen in a letter to the Baltimore *Sun*, dated April 30, 1900. They are here abstracted. In answer to a statement made that Senator Gallinger had been an eminent practitioner for thirty years, Dr. Keen replies: "Senator Gallinger has not been a practitioner of medicine for a number of years. I am sure that were he familiar with the progress of medicine, and especially of surgery, within the last twenty years he would not have stated that 'the belief was expressed by competent authority (?) that little real benefit had come from all the mass of the more horrible experiments.'"

Referring to two statements in the interview he says, "Senator Gallinger says that American physicians should not 'object to the inspection and regulation which the accomplished and able faculty of England accept without question or remonstrance.' As a matter of fact, almost the entire profession of Great Britain have protested and remonstrated against their existing act. At the recent hearing on the Antivivisection bill before the committee, of which Senator Gallinger himself was chairman, Professor Welch, of Baltimore, presented letters from Lord Lister, Sir Michael Foster, M.P.; Sir T. Lauder Brunton and Sir T. Grainger Stewart, four of the leading medical men in Great Britain, representing the surgeons, physiologists and physicians, who showed how obstructive to progress the British law is, and how deleterious such a law would be if enacted in this country.

"Another statement by Senator Gallinger is still more indefensible; namely, 'Not only in foreign countries, but in the United States, human vivisection has been practised to a considerable extent; children and women in charity hospitals being inoculated with loathesome diseases for the sole purpose of watching them suffer and die.' The only evidence as to human vivisection which was alluded to at the hearing was a pamphlet published by the miscalled 'American Humane Society,' dealing (in many cases with singular inexactness) with all the instances which their drag-net has been able to cull from the medical literature of the world. Instead of human vivisection being practised 'to a considerable extent,' that pamphlet could give only two instances of anything resembling experiments on human beings in this country—one in Massachusetts and one in Maryland. The first was a series of experiments on puncture of the spinal cord; the other on the use of thyroid extract. Even these in my opinion were reprehensible. The others mentioned in the pamphlet alluded to were expressly condemned by Dr. Osler, myself and others at the time of the hearing. Not a single instance of the 'inoculation of children or women with loathesome diseases' in the United States was adduced. The whole impression of the interview upon the public is that human vivisection and the inoculation of loathesome diseases is not uncommon in the United States. How far this is from the real truth I have stated.

"It is strange that Senator Gallinger has introduced a bill for the 'regulation of scientific experiments on human beings in the District of Columbia.' Regulation implies certainly approval of such experiments under stated conditions, as is indicated throughout the bill. The medical profession as such utterly repudiates any such experiments on human beings, which Senator Gallinger seems to approve. Moreover, it is difficult to conceive of one's regulating a thing which does not exist. In the District of Columbia not a sin-

gle instance of human vivisection has occurred, nor do I believe any ever will occur. The whole object of the introduction of the bill is evidently for the moral effect which it would produce in making the community believe that there is in existence a practice which needed to be regulated and indirectly to help the anti-vivisectionists in their cruel campaign against humanity.

"I regret very much that Senator Gallinger has made an attack upon the noble profession to which we both belong. To say that 'there is an ambition on the part of many operators to make new discoveries with little regard to the percentage of fatalities under the knife,' that 'no chance is too desperate for the modern surgeon to take,' that 'conscience has very little to do with the matter as a general thing,' and that patients who enter hospitals should 'leave hope behind,' are slanders upon the profession, which I most indignantly deny. I know the surgeons of this country well, and a more conscientious body of men I do not know anywhere. They are honest in the statement of their results, they do not hesitate to acknowledge their mistakes, and they can face their patients here and hereafter with as clean a conscience as any set of men in the country. Senator Gallinger must have been singularly unfortunate in his relations with medical men to have formed so low an opinion of their moral character."

SEMI-CENTENNIAL JUBILEE OF THE WOMAN'S MEDICAL COLLEGE OF PENNSYLVANIA.

Exercises celebrating this event were held in Philadelphia in connection with the forty-eighth annual commencement, May 16-18, 1900.

At the commencement May 16th the degree of Doctor of Medicine was conferred upon 26 graduates. The address to the graduates was delivered by Mary Putnam-Jacobi, M.D., of New York. The speaker advised the cultivation of the laboratory habit of mind by young physicians. This leads to the resolving of symptoms into groups of phenomena having a common basis; it causes the social and personal importance of the patient to disappear; and it excites interest in trifling ailments that involve biological principles. It would seem incredible, if not known to be true, that anti-vivisectionists and others should clamor for the repression of physiological experimentation. The experimenting which needs repression is that of Christian Scientists upon helpless children.

A portrait of Dr. Ann Preston was presented to the Corporators by the alumnæ of the College. Dr. Preston was the first woman to hold the position of dean of the college and was largely instrumental in founding the Woman's Hospital connected with that institution.

Wu Ting Fang, Chinese Minister to the United States, then delivered an admirable address. He had thought that men enjoyed a monopoly of the professions until coming to this country, and he did not know that women had schools of medicine exclusively for themselves until he received the invitation for this day, and admitted that it was largely curiosity which led him to accept it. The question of professional training for women is different from higher education; but in many respects medicine, of all the professions, is best suited to women. If only medical missionaries had been sent to China, much less trouble would have occurred, as these missionaries carry their own recommendation and people accept them. The speaker thinks it a great pity that the medical works in the Chinese language cannot be used owing to difficulty of translation. He advises young women doctors to go to China where there is room and demand for many such workers.

At the first session of the Alumnæ Association at 10 A.M., May 17th, a "History of the Association" was read by Elizabeth C. Keller, M.D., of Boston. The doings of the Association were traced from its founding in 1876. A strong point in its history is the interest taken in students of the College, many sums of money being loaned to worthy native students to enable them to complete the course.

"Women's Work in the Care of the Insane" was the subject discussed by Calista V. Luther, M.D. Of the 133 public institutions in this country, only 37 have women-physicians. Pennsylvania is the only State containing an institution where the woman's department is entirely under the management of women. This is the Norristown Insane Asylum. Most insane women should be treated by their own sex and none but women admitted to their presence. The speaker does not believe that insanity is commonly due to disorders of the generative organs. There was a time when every ache and pain was referred to these organs and too much treatment was instituted. Now the pendulum is swinging the other way. Of late less is being done and said about the generative apparatus and more attention is being given to hygiene, gymnastic exercises, and out-door life which shall make the speculum and the probe and the pledget cease to be an indispensable part of a woman's training and outfit. In reply to questions sent out, many women-physicians in hospitals for insane do not think uterine disease a common cause of insanity. Although erosions heal and prolapse are cured, physically no benefit is obtained. In cases seen personally only one had any unsoundness of the generative apparatus. In cases of amenorrhea due to anemia, etc., the menses return when the patient's general health improves, but the mental state does not improve in the slightest with the return of menstruation. The speaker mentioned the work of some women and their gratifying success in introducing the personal element in the cure of the insane. This is having classes in sewing, giving dances, games, teas, etc. Many cases also do better in small institutions where they are sent "for a rest," etc., and really do not know they are in an asylum.

The morning session was ended by reports of alumnæ practising in various foreign countries. In India the exanthematous disease are the most common, eye-diseases are next in number, and leprosy is prevalent. Two hospitals and five dispensaries have been founded and also a woman's medical training-school. It is very difficult to secure operation for fibroid or ovarian tumors. In Russia the right to practise medicine was first granted to women in 1872. The Government now puts them on a level with men. Country doctors generally have a small hospital of 10 or 20 beds. There are 15 women-inspectors of schools in St. Petersburg, each having about 25 schools. One private hospital is entirely managed by women. In Persia a dispensary has been established in which 30 to 80 cases are treated daily. Eye- and skin-diseases are seldom absent and one-third are gynecological cases. Physicians are respected in any part of Persia. Seven native young men have been trained to assist. The women marry so young they cannot be used as nurses. In Sweden the schools where women may study medicine are all co-educational. A degree only allows them to practise privately, not admitting to government positions as in the case of men. Most of the women-physicians are devoted to gynecology. There are several Government endowment funds for women-students and the public generally receives them well. In Holland the universities are open to women the same as to men. Co-education has given no trouble.

The afternoon session was devoted to reports from various medical colleges. In detailing the history of the New York College and Infirmary for Women, Dr. Emily Blackwell stated that co-education seems to be the way of the future. The position of women in such schools, from their small numbers, etc., is more difficult than that of men, but this will be overcome. The full advantage of co-education will come only when there is co-operation throughout the management and teaching of these schools as well as co-education on the benches.

The history of the Woman's Hospital of Philadelphia was read by Dr. Ella B. Everitt, resident physician. The hospital was established in connection with the College in 1861 to furnish a place where women might be treated by physicians of their own sex, to furnish clinical instruction for students, and to train nurses. It now has 130 beds. In 1899 1038 cases were treated and 5425 dispensary visits were made. In 1875 two ovarian tumors were removed from patients in the hospital by Dr. Emmeline Cleveland, these being the first major surgical operations performed by a woman. During the Spanish-American war 97 soldiers were cared for in the hospital.

The morning session of May 18th began with the President's address by Dr. Lilian Welsh, of Baltimore, on "Present Tendencies in Medical Education in the United States." Dr. Welsh believes that the tendency in this country is to regard a four years' course, of at least 9 months each, devoted to the exclusive study of medicine, as the standard to which all good schools must in the near future conform. Preliminary education is needed and even the graduates of reputable literary colleges, unless the work leading to their degree has included physics, chemistry, and biology, are not prepared to begin the study of human anatomy and physiology. To enforce a higher standard of admission will require vastly improved teaching facilities in the great majority of medical schools. Laboratory methods are being introduced in all departments of teaching and soon the man who teaches practice or surgery cannot be a busy practitioner who takes a few hours for didactic lectures. Instead, he must be a salaried teacher who investigates in his own laboratories. The most important event in medical education in the last decade was the organization of the Johns Hopkins Medical School. The study of medicine is essentially graduate-work. Opinions may differ as to whether the curricula of colleges designed to give a general education should be modified by sex, but the question of what should constitute a medical curriculum is sexless. The next fifty years will witness an increased struggle for existence on the part of the independent medical schools. The survival of the fittest will depend upon their power of adapting themselves to a progressive standard of instruction; this adaptability in the case of individual schools will be possible only with an ample endowment fund. Medical schools not heavily endowed will find it difficult to maintain an honorable existence.

The Dean, Dr. Clara Marshall, read a paper upon "The Past, Present and Future of the College." Mention was made of the time when students of the College were excluded from all the hospitals of the city. Now they are admitted to clinical lectures and instruction in nearly all of them. The Woman's Medical College was one of the first to establish entrance examinations and inaugurated the four-year course in 1893. In the State Board examination in June, 1899, it was the only college whose representatives met with no failures. There are now 66 instructors, the large majority of these being women. The graduates have met with success as missionaries; they have founded hospitals; they have read important papers before societies. Not enough of these papers have been published to give them a true recognition. The future success of the college will depend not so much upon the number of students as upon the endowment that can be secured.

The remainder of the forenoon, and all of the afternoon, session was devoted to the reading of reports from alumnæ in the various States of the Union. In California women are welcomed in medical societies, but few hold public appointments. In Oregon only one woman physician has held public office. One graduate received an appointment as hospital interne because of her class-standing, but her professors advised her not to accept it, this advice being taken. This

fairly represents the sentiment of the State. In Colorado public positions are held by women and their position depends upon ability. Virginia is the most conservative State, men and women alike being opposed to the enlarging of woman's sphere.

Officers of the Alumnæ Association elected were: President, Dr. Elizabeth L. Peck; vice-president, Dr. Ruth Webster Lathrop; secretary, Dr. Gertrude A. Walker.

Thus closed the fiftieth anniversary of the Woman's Medical College of Pennsylvania. The College has a record of which it is justly proud. The reports from all parts of the world show that women-physicians are slowly but surely gaining recognition and that this recognition is essentially due to merit and ability and not to social or political influence.

CORRESPONDENCE.

OUR LONDON LETTER.

[From Our Special Correspondent.]

London, May 17, 1900.

THE FIRST MEDICAL VICTORIA CROSS OF THE CAMPAIGN—THE RETURN OF THE FIRST CONSULTANT SURGEONS FROM SOUTH AFRICA—STORM OVER MIDWIVES' BILL SUBSIDING—A SURGICAL DIARY OF THE SIEGE OF KIMBERLEY—STEPHEN PAGET'S BOOK AND THE "ANTIS"—TYPHOID AMONG BOER PRISONERS AND ENGLISH TROOPS IN THEIR LAAGERS—NATIVE "SCHOLARSHIPS" AT THE LIVERPOOL TROPICAL SCHOOL—THE MOSQUITO EXPERIMENTS IN THE CAMPAGNA.

The medical hero of the hour is Major Babtie of the Royal Army Medical Corps whose gazetting for the Victoria Cross was announced a short time ago. When we say "medical hero" we mean not simply a hero in medical circles, for the fame of his exploit has spread far beyond these and general satisfaction is expressed that in him the heroism of the non-combatant in battle is to be adequately and efficiently recognized. The story of his feat has been told so often that little more than a reference to it is needed. The reckless, headlong dash forward of a heavy battery, far in advance of the skirmish line even, let alone the infantry whom they were supposed to support, as if they expected to mow the Boers down with their gun-wheels, war-chariot fashion. The sudden burst of a murderous sheet of lead and flame out of a green mimosa wood, literally mowing down every living thing before its sweep and covering the little plain with dead and dying. News is brought of the disaster and Babtie immediately volunteers to go to the aid of the wounded. Three times is his horse shot under him ere he reaches the shallow gully-trough into which most of the wounded had crawled or been dragged, but out he ventures from its shelter time after time under a perfect storm of bullets until all had been brought into shelter, among them Lieutenant Roberts, the son of the Commander-in-Chief. There for seven sweltering hours he plied the water-bottle and the morphine tablet, the only shade from the broiling African sun being a letter out of his pocket which he held over the face of poor young Roberts. Major Babtie will do the coveted decoration almost as much honor as it will him.

The cause of the return from South Africa of the two most distinguished consulting surgeons, who have gone to the front, before the war is apparently more than half over is giving rise to some little comment and speculation. The explanation, however, is probably that all the medical arrangements were found to be working so admirably that, after a thorough tour of inspection and ascertainment of the fact, they were really perfectly free to return home with a clear conscience. Considerations of health also played a part in both instances, as the strain of service in the field told heavily upon Sir William MacCormack's advancing years and Mr. Treves had suffered severely from dysentery. Even the personal experience of the latter shows the effects of the disease; he went out the picture of florid vigor with a most generous waist-line; he returns looking as if he had lost fifty pounds, with diminished color, and whitened hair.

Of course, as a matter of fact, the great men were merely sent out by the Government, or rather the War Office, in a sudden spasm of fright and repentance for the long and obstinate neglect of the Army Medical Corps and its needs in the hope of "saving its face," as the Chinese say, by a burst of liberality. But the despised Army Medical Corps has returned good for evil by working so admirably that the consultants, as most of them have frankly confessed, found that there was really little for them to do except to cordially commend the efficiency of its management. Of course, it has been a great satisfaction to the families and friends of the soldiers to know that they would have at their disposal the very best advice and highest skill in the profession, but the campaign so far has been anything but "an operators' war," the vast majority of cases recovering under a policy of strict cleanliness and masterly inactivity, even from the most appalling and extensive injuries. "Tom" Smith's parting advice to one of the consultants, "Don't do any operations," might be taken as the surgical motto of the campaign.

A most animated tempest in a tea-pot is still raging in the ranks of the profession over the Midwives' Bill. A considerable number, possibly the silent majority of the profession seems to have drifted into the position that midwifery legislation of some sort is absolutely inevitable, indeed, necessary, and that perhaps this Bill has as few objectionable features as any which is likely to be passed. A few energetic spirits like Victor Horsley are doing their utmost to amend the Bill while there is yet time, while another element in the profession is holding meetings and

denouncing the Bill and all who have even tacitly approved of it. This last element probaly represents a class of practitioners who would be most keenly affected by the provisions of the Bill and who are least fully represented upon the great governing bodies. Their demand, however, for the resignation of Dr. Stephen Glover, one of the direct representatives of the profession upon the General Medical Council, because he did not oppose the Bill, is universally disapproved of and the refusal of the gentleman to accede to their request, with its gentle sarcasm, fully endorsed. The battle has now reached the correspondence stage in the journals and will probably soon die out, although Mr. Horsley fiery pen has just been drawn into the fray and his energy as a letter-writer is as phenomenal as in every other capacity. The Bill seems almost assured of passage now and with some most necessary amendments will make a decided improvement upon the present haphazard state of affairs, almost like that of the profession before the Medical Practice Acts.

The medical side of the late stirring times in South Africa is soon to be represented in permanent literature as Dr. Evelyn Oliver Ashe, Surgeon to the Kimberley Hospital, is about to publish a diary of the siege of Kimberley through Messrs. Hutchison, the well-known London publishers. It is really to be hoped that some publisher will succeed in inducing Mr. Treves either to edit and reproduce his brilliant, graphic letters to the *British Medical Journal,* which have attracted such wide attention, or in some other way to make a book out of his interesting experiences.

A furious discussion is still raging over Stephen Paget's admirable little book upon animal experimentation. This was a quiet, clear, and extended presentation of the simple facts of the results of vivisection in the direction of serums, antitoxins and preventive medication generally, and of course caused shrieks of dismay in the "Anti" camp. Their permanent secretary, Stephen Coleridge, has taken advantage of a review of it which appeared in the *British Medical Journal* to pour forth most voluminous replies and corrections which the editor with great forbearance and courtesy has permitted to appear *in extenso.* In this he is probably right, for the more the matter is ventilated, the more the facts will tell and the truth prevail, and, while discussion of this sort is superfluous for the profession, the columns of both the *Journal* and *Lancet* are watched with hawk-like keenness by the daily press here and anything of public interest copied and commented upon at once, so that indirectly the public will be reached and benefited.

The arrangements for the malaria experiments announced by Dr. Patrick Manson are rapidly progressing. The mosquito-proof hut has been constructed and will shortly be sent to the Campagna. Dr. Sambon, a lecturer, and Dr. G. C. Low, a student at the Tropical School of Medicine, have volunteered as "subjects" and will occupy the hut, devoting their time to "mosquito-dodging." This sounds like a difficult, if not almost impossible, task, but may possibly prove feasible on account of the limited and regular hours of flight of the Anopheles. Bites from Culex, however, are almost certain to be received and is it going to be always possible to make a determination of the species on each occasion? The complete escape of the experimenters would be a triumphant demonstration of the mosquito-theory, but the infection of one or even both of them would not necessarily disprove it, in view of the numerous chances of accidental bites.

The scourge of enteric fever among the Boer prisoners at Simonstown seems to have reached its limit and to be largely confined to those prisoners who were infected before entering into captivity. A significant corroborative piece of evidence as to the origin of this disease is found in the fact that the British regiments which occupied Paardeberg after Cronje's surrender were severely attacked by typhoid from one to three weeks later, all the available drinking-water of the region having become contaminated from this nest of pestilence with its living filth and decaying carcasses.

The plucky little Liverpool School of Tropical Medicine is again to the front. Not content with offering instruction in these most important diseases to English and other European students, its chief supporter and financial mainstay, Mr. Alfred G. Jones, has now brought forward a scheme whereby the native students of tropical colonies can be brought to Liverpool and obtain a medical training at a small expense and thus spread the knowledge gained by the researches of the staff where it will be most effective for good. Through his great steamship company (Elder, Dempster & Co.), passage at exceedingly low rates is offered and it is hoped that many will avail themselves of the scheme. The estimated cost of the complete course, $3000, even although it includes living and traveling expenses, sounds high to American ears. It is, however, little more than half the probable average cost of an ordinary English medical education.

PLEURISY COMPLICATING APPENDICITIS—A QUICK DIAGNOSIS OF RABIES—THE CHOICE OF OPERATION IN RENAL TUBERCULOSIS—PERFECT ASEPSIS SECURED BY THE USE OF RUBBER GLOVES—A SIMPLE METHOD OF DETERMINING THE PRESSURE IN PNEUMOTHORAX—SECONDARY INFLAMMATIONS FOLLOWING THE GRIP—ANGIOCHOLITIS WITHOUT ICTERUS—ADDISON'S DISEASE IN A CHILD SIMULATING PERITONITIS.

At the Academy of Medicine, April 10th, Dieulefoy called attention to a complication of appendicitis which he has frequently observed. It

is an infection of the pleural cavity with the same agent which causes the appendicitis. He therefore proposed the name appendicular pleurisy. A study of his cases convinced him that the infection spreads by the lymphatics of the peritoneum to the right hypochondrium, passes through the diaphragm and enters the pleural cavity. This complication occurs between the eighth and the fifteenth day after the onset of the disease. As the infection does not begin to travel upward until three or four days after it begins in the appendix, the pleural complications will not be found in cases in which the focus of infection is early removed. The premonitory symptoms are pain in the region of the liver and an apparent increase in its area of dulness, anxious breathing, etc. The pain may radiate to the right shoulder. These symptoms are due to the inflammation about the liver and under surface of the diaphragm. Pleurisy of this sort is usually suppurative and of large extent. In the beginning pleuritic sounds are heard, but these rapidly give way to the signs of pus. The amount of fever is variable. The constitutional symptoms are grave, although they are not wholly due to the pleurisy. Edema of the chest-wall has been observed. The trouble may be mistaken for gangrene of the lung due, possibly, to tubercular perforation. An exploratory puncture will serve to distinguish between them. If pus is obtained the operation for empyema should be performed at once.

Cornil described the method by which Babes of Bucharest makes a quick diagnosis of rabies by a histological examination of the medulla of the suspected dog. A fragment of the brain of the sick dog is injected into the head of a rabbit while a section of the dog's medulla is hardened with formalin. In twenty-four hours sections are cut from this and stained with carbolic fuchsin or methyl blue, dehydrated, mounted and examined with a low power. If this examination shows the presence of embryonic nodules in the gray substance, together with an embryonic condition about the vessels, or everywhere, with chromatolysis of the nervous elements, one may safely conclude that the dog was mad. In the cases in which these signs were found the inoculated rabbits developed rabies, while the rabbits inoculated with the brain-substance of sick dogs whose medullæ did not present the signs above mentioned failed to develop rabies.

At the session of April 17th Nocard spoke of the importance of this method of diagnosis which enables the physician to take some definite measures with reference to the persons bitten by the dog within twenty-four or forty-eight hours of the time of the accident. Unfortunately, however, investigations of other histologists have shown that the lesions mentioned in the medulla of the dog, while almost invariably found when the animal succumbs from his malady, are not present if he is killed in the beginning of his attack. However, if the histological examination yields positive results they are none the less valuable.

At the Society of Surgery, April 4th, Pousson spoke of surgical intervention in renal tuberculosis. He practised nephrectomy seven times with seven successes and nephrotomy four times with one success. Two patients died and secondary nephrectomy was performed upon the third.

Reynier agreed with Pousson that nephrectomy is preferable to nephrotomy, provided the other kidney is sound.

Tuffier said that the treatment of renal tuberculosis ought to vary according to the condition of the patient. Thus, in case of tuberculous perinephritis it may be unwise to remove the kidney, because of the difficulty in determining the condition of its fellow.

At the session of April 25th Quénu gave the results obtained by him during the past year, rubber gloves having been used at all operations. There were 102 laparotomies with 14 deaths. In 9 of the fatal cases the condition requiring operation was a septic one. The remaining 5 deaths could in no sense be attributed to any lack of asepsis either at the operation or subsequently.

Tuffier said that under no circumstances would he allow himself to be operated upon by a surgeon who had just been handling a septic patient. He believes in the use of rubber gloves in septic cases. For other cases he prefers thread gloves which certainly greatly reduce the danger of infection from the hands of the operator, while allowing him to proceed rapidly—an important point in many operations.

At the Medical Society of the Hospitals Beclere called attention to a simple method of determining the pressure in pneumothorax, the same being also a safe method of treatment. A hypodermic needle is thrust into the pleural cavity between the ribs. Its external end is connected by a short rubber-tube with a glass-tube sunk to its middle in a glass full of water. The height of the water in the tube will then show whether or not the pressure in the pleural cavity is increased. If gas is present the apparatus will permit its escape without the risk of cutaneous emphysema which so often follows where a trocar is used to evacuate the gas.

At the session of April 27th Faure said that the grip is often followed by inflammations of the nasopharynx, frontal sinuses, tonsils, etc. Such secondary inflammations are accompanied by the symptoms which mark the primary infection, *viz.*, fever, general malaise, night-sweats, etc. In the intervals between such attacks one may observe slight rises of temperature which show that the infectious process has not been wiped out. In this manner one can explain that state of persistent malaise which so often follows the grip and which disappears completely if the nasopharyngeal inflammation is treated by local antiseptics and the patient is given injections of antistreptococci serum. The author maintained that the rebellious neuralgias and rheumatic pains and various neuropathic symptoms which so often complicate the grip are due to the streptococcic toxins secreted in the mucous membrane.

Rendu, while agreeing with Faure's pathology of nasopharyngeal lesions, did not advocate the use of antistreptococcic serum, because it is impossible to say just what streptococcus is at work and to give serum from a different variety can produce no good result.

P. Lereboullet mentioned two cases of subacute angiocholitis which ran their course without icterus.

Netter reported the occurrence of Addison's disease in a child aged thirteen years. While in full health he was seized with chills, vomiting and diarrhea, fever, prostration and acute abdominal pain. The face, the pulse, the fecaloid vomiting and the temperature seemed to indicate peritonitis. A light pigmentation of the skin alone suggested Addison's disease, but nothing in the history pointed to this diagnosis. The patient died in three days after the attack and there was found an old tuberculosis of the suprarenal capsules. Peyer's patches were swollen but not ulcerated. The spleen was very large and scrapings of its pulp gave a pure culture of streptococci.

SOCIETY PROCEEDINGS.

AMERICAN GYNECOLOGICAL SOCIETY.

Twenty-fifth Annual Meeting, Held at Washington, D. C., May 1, 2 and 3, 1900.

(Continued from Page 807.)

Third Day—May 3d.

Bronchial Disease and Ether Anesthesia.—Dr. Thaddeus A. Reamy of Cincinnati was the first paper read a paper on this subject. It will appear in full in a subsequent issue of the Medical News.

Dr. McLean of New York opened the discussion and said that it was most important to keep the operating-room at a high temperature and to avoid unnecessary saturation of the patient with ether. The anesthetizer should pay close attention to the patient and not do anything else.

Dr. Harris of Paterson said that it was very important to have perfect quiet in the room where the anesthetic was being administered, as any noise diverts the patient's attention and makes the time required to produce anesthesia very much longer.

Dysmenorrhea and Appendicitis.—Dr. Archibald McLaren of St. Paul read a paper on this subject. It will appear in full in a subsequent issue of the Medical News.

Dr. Skene of New York opened the discussion and said he had seen ovarian pain due to appendicitis cause dysmenorrhea ovariana. This pain would disappear on removal of the appendages. The best method of removal of the appendix is by the use of hemostatic forceps, as by heat and pressure one can absolutely close the lumen of the appendix. There is no danger of hemorrhage or septic absorption, as the stump will undergo organization and so relief is permanent and absolute.

Dr. Smith of Montreal said that he had found concomitant appendicitis in nine cases when operating for salpingitis and ectopic gestation. The differential diagnosis between salpingitis and appendicitis is most difficult, and the fact that they may both be present is an argument against the vaginal route. His method of operating on the appendix is to cut it off on a level with the colon, then close the resulting hole with Lembert sutures exactly as if it were a bullet wound. In young girls a pus-tube is often the result of appendicitis. This is caused by the appendix being forced down on to the Fallopian tube by constipation and by the migration of the colon bacilli from one to the other.

Dr. McLaren closed the discussion by saying that he fully agreed with Dr. Smith's remarks. In these cases the disease is usually confined to the right tube while the left is perfectly normal.

Demonstration.—Dr. Philander A. Harris of Paterson, N. J., was next on the program and after demonstrating the advantages to be gained by the use of his chart for the determination of pelvic asymmetry from a very simple method of external pelvimetery, spoke of the desirability of employing a certain background in the photography of pathological specimens and said he had devised such a background, consisting of cardboard divided by lines into one-inch squares. The specimen to be photographed is pinned on this background and its exact size is thereby quickly shown.

Dr. Smith of Montreal opened the discussion and said that he had had good results from the method of Dr. Pich of Berlin which consisted in tying the specimen to be photographed on a galvanized wire-screen having a one-inch mesh. This accomplished the same result.

Dr. Van de Warker of Syracuse said that he had had good results by suspending the specimen in water beside a rule and then photographing it from above.

Dr. Goffe of New York said that Dr. Pryor had used the wire screen several years ago and that the procedure was original with him.

Face Presentations.—A paper on this subject was read by Dr. Malcolm McLean of New York. It will appear in full in a subsequent number of the Medical News.

Dr. Greene of Boston opened the discussion by saying that he had never seen a case of face presentation with the chin posterior in which he had not been able to deliver either with forceps or with his own hands.

Dr. Murray of New York said these cases are very infrequent and that when there is an abnormal presentation the fault is either in the child or else there is a defect in the mother's pelvis. A careful vaginal examination will generally show exactly what is wrong and then the appropriate treatment may be applied. If the case be let alone, the child or the mother, or perhaps

both, may die. He has used Dr. McLean's method with success. When cephalic version fails, podalic version should be tried, and if this fails the only alternative is to do either a Cæsarean section or else one of the destructive operations.

Dr. Reynolds of Boston said that he had seen nature convert a vertex presentation into a chin presentation when the head is low down in the pelvis. This operation at the brim of the pelvis is a well established procedure, but when ordinary corrective measures fail symphysiotomy is indicated. This will give a marked increase in space and permit labor to go on to a normal termination.

Dr. McLean closed by saying that he wished to emphasize the fact that in his cases the head bore the ordinary relation to the size of the pelvis and was not small, as many had believed. It was an average case and not one of a very small child in a very large pelvis—in fact the latter was below normal size. His method simply consisted in taking full advantage of the soft parts of the pelvis that can yield to pressure.

The Society then adjourned to meet at Marshall Hall in the afternoon.

Anniversary Exercises.—Dr. Thomas Addis Emmet read a paper entitled "Personal Reminiscences Associated With the Progress of Gynecology," in which he said that he had read the first paper at the first meeting of the Society at its foundation on September 3, 1876, taking as his subject the Etiology of Uterine Flexions. There were twenty-five members at that meeting and since then two-thirds of them have died. The beginning of the Woman's Hospital in New York was a small building for the cure of vesicovaginal fistulæ and since its foundation over 600 cases have been cured there and some were discharged as incurable. To-day no fistula is incurable, and many can be prevented. Dr. Sims was attached to this Hospital for five years before going to Europe and his departure was a great loss to the profession as he never again had the opportunity for study. His speculum was first tested there and proved a useful addition to the gynecologist's armamentarium. From 1859 to 1869 the author was in charge of the Woman's Hospital and did much more work than Dr. Sims had ever done there as the latter had never kept the histories or followed up the cases. It was during his service with Dr. Sims that he (Dr. Emmet) devised many of the instruments which bear his name. In 1862 he devised the hot-water vaginal douche as a substitute for ice water which had been used entirely previous to this time, and it proved to be one of the greatest advances in the history of medical science. Soon after Dr. Sims' departure two very difficult cases of vesicovaginal fistula presented themselves. He operated on them both and cured them. Then he sent for thirty cases which Dr. Sims had pronounced incurable and operated on them all with success. In 1868 he described his method of forming a new urethra after it had been destroyed by sloughing. He has since done it with entire success in fifty cases. At the time this work was published he had cured long-standing cystitis by forming a permanent fistula into the vagina, had removed vesical calculi through an incision made in the vesicovaginal septum, and pointed out the dangers of incontinence following dilatation of the female urethra, had removed pedunculated fibroid tumors by section and other small growths by traction, had made endoscopic examinations, had made a study of prolapse from the simple cases to those in which there was complete procidentia and described the different plastic operations on the vagina. In 1863 he described his method of operating on the posterior wall of the vagina which he had originally employed in a case of vaginal prolapse, so every operation for the repair of lacerations of the perineum is only a modification of his method. He has cured thousands of women who have suffered from prolapsus uteri and in over two hundred of them the uterus was entirely outside of the vagina. In several of these cases the woman subsequently gave birth to a child and no recurrence followed. There is a plane in every woman's pelvis which bears a most important relation to the blood supply. Any alteration of this plane prevents the blood from leaving the pelvis as easily as it enters it and passive congestion follows as a natural course. Ventrosuspension often relieves many women, but this method is purely empirical for the reason that the uterus seldom remains where it was placed at the operation, the attachment invariably lengthens. Plastic work on the vagina is much better as it more often results in a permanent cure. In 1862 he recognized lacerations of the cervix and also the fact that they cause often a hypersecretion in the uterine canal as the result of some pelvic inflammation. In these early days much more attention was paid to ultimate effect rather than to cause. He was the first to observe the intimate relation of pelvic peritonitis and cellulitis to uterine disease. He wrote his first book, which represented an entirely new departure based on original research, from the existing theories of gynecology in 1879 and offered it to a well-known publishing-house which refused it on the advice of one whom he had believed to be his friend. He then published it himself at his own risk, and since then it has gone through many editions. At this time he also showed that unless the cellular tissue be infiltrated below the dip of the peritoneum no peritonitis can exist. In 1878 he published a paper on vesicovaginal fistula, showing that it was the result of sloughing caused, as a rule, by the use of ergot during labor. Since then ergot has gone entirely out of use and vesicovaginal fistula has become a very rare condition. Before that time there used to be forty beds in the Woman's Hospital always full of these cases, but in the last two years he has seen only two cases. He cured from 96 to 97 per cent. of the supposedly incurable cases. At this time he showed the use of the pessary and how in many cases the vaginal tam-

pon may be substituted to advantage, but the pessary is still useful in a certain class of cases. The Trendelenburg posture was shown to be of value, especially in those cases where the normal circulation in the pelvis is opposed to the laws of gravity. Nature when let alone cures many cases of laceration of the cervix, but where she fails the best operation is a conical amputation which the author originated, as well as pointed out the very close relationship existing between lacerations of the cervix as a cause of epithelioma of the cervix. He was the first to call attention to the value of uniting the torn ends of the sphincter muscle in all cases of true laceration of the perineum, thereby restoring continence. When this is not done a cicatricial band takes the place of the ununited ends and the operation is often not followed by relief. The past twenty-five years of progress in gynecology have been rendered brilliant through antisepsis rather than through operative skill. Too many of the younger men in the profession are so anxious to operate that they neglect the careful preliminary study of medicine in general. In 1860, when he first commenced to do ovariotomies, if the patient died there was always a coroner's inquest for the surgeon to face. Since then he has performed more than 1500 laparotomies, two-thirds of which have been for the relief of ovarian tumors and many were done before the discovery of the principles of antisepsis. Then it was the custom to tap the tumor and to wait until the peritoneum became tolerant before operating. In many cases operation was only done as a last resort. He then outlined the different methods that have been used in treating the stump after hysterectomy and also considered the relative advantages of the different methods of suturing. He said his method of treating pus-tubes was to make a vaginal incision and, after incising the pus-tube, stitch it to the vaginal incision and so secure perfect drainage. When he began the study of medicine, fifty-four years ago, peritonitis was treated by doses of calomel and soda followed by saline purges. Then Clark's treatment by opium was introduced and was responsible for an enormous number of deaths, and to-day the accepted treatment is again by saline purges and it is most successful in the few cases that occur. In 1882 he removed a uterus for fibroid tumors through the vagina, having first made an abdominal incision, and the woman died. The greatest advance in the operation of hysterectomy has been the introduction by Stimson of the method of tieing the uterine and ovarian arteries. He considers that Dr. Kelly has done more than anyone else to make hysterectomy possible. He has just had a case in which there were nine fibroid tumors in the uterus and the complication of pregnancy. He removed them very gently, the woman did not abort, and he had less trouble in doing it than he used to have in removing a simple para-ovarian cyst.

"The Status of Gynecology in 1876 and in 1900" was the title of a paper read by Dr. Alexander J. C. Skene of New York. (See page 769.)

Dr. James R. Chadwick of Boston then read a paper on "Reminiscences of the Foundation and Early Years of the Society." Dr. Chadwick, who was one of the founders of the Society and its secretary for many years, gave an account of how the Society was formed and related anecdotes of the men, now dead, who were instrumental in the good work that the Society has done. "The Personal Factor in the Work of the American Gynecological Society." Dr. E. Van de Warker of Syracuse read a paper on this subject. "A Foot-Note," by Dr. Thaddeus A. Reamy of Cincinnati, consisted in a retrospect of the work of the Society and an outline of what may be expected of it in the future.

AMERICAN NEUROLOGICAL ASSOCIATION.

Twenty-sixth Annual Meeting, Held at Washington, D. C., May 1, 2 and 3, 1900.

First Day—May 1st.

President's Address.—This was the opening paper of the first day's session. (See page 819.)

Christian Pseudoscience and Psychiatry.—Dr. Smith Baker made reference to the *Christian Science Journal* for January containing an article by Judge Joseph R. Clarkson, of Omaha, who stated that "Christian Science makes stronger, healthier, more unselfish, more honest, contented, holier, purer poor people;" through Christian Science there have been, as well as can be estimated, more than a million cases of healing of every sickness; that in the opinion of the best qualified judge there is no disease Christian Science cannot meet, arrest and destroy. Dr. Baker suggested that if a disease is acute it must come within one of two classes: it is either natural, self-limited or easily cured, or the diagnosis is in error. It could not be supposed that Christian Science can cure a real fracture, or dislocation or crushed bone. Nor can it be believed that a case of typhoid fever, smallpox or pneumonia is under the control of the "healer."

Imperative Ideas in the Sane and Their Management.—Dr. Edward B. Angell read this paper and pointed out that in the normal mind there are words, phrases, emotions, or ideas, which recur and force themselves against the will. When the mind is morbid, these demands of imperative ideas become a disease against which the most strenuous efforts of the will seem impossible. The essayist's idea was to ascertain how far our present knowledge of these imperative ideas will enable us to recognize their significance. In order that these morbid ideas may be investigated, it is essential that the mind be studied in its automatic activity, a state which obtains in conditions of sleep, hypnosis, somnambulism, hysteria and insanity, and during these conditions normal evolution is largely or entirely suspended.

Dr. Angell believed hypnotism holds out a certain form of relief, and only through its influence a state of primary disturbance, existing as a sub-

conscious idea in the mind of the patient, could be ascertained. In the use of hypnosis the patient should invariably be carefully awakened and left in a calm mood at the end of the séance.

In discussion, Dr. Smith Baker suggested that as a prenatal condition there are certain conditions of the mind in the form of a stress brought about by deprivation, as in sexual obsession, when one or the other parent or both have lived a life of absolute sexual stress of the order of deprivation; or, during the time of travail, when the woman is eager for property and yet is deprived of obtaining it. That condition seems to be one which will produce a weak spot in the child, where the imperative obsession will be developed later on. The essayist was somewhat skeptical about hypnosis; he would rather endorse the more open means of educating the mind by familiarity with literary works, essays, some particular new field of mental activity.

Dr. Knapp was of the opinion that Dr. Angell's proposition of imperative conception and fixed idea cannot be carried out in practice. To remove a fixed idea by hypnosis appears like applying a spinal brace for the cure of a weak back.

Dr. S. Weir Mitchell spoke of a case of a woman who when she turned over a book, for instance, was imbued with a desire to change it a certain number of times; with that impulse she would have associated in her mind a certain relative. If she thought of her cousin, she would turn the book three times; if her husband she did it seven times. When a child she was disposed to shrug her shoulders and connected the latter peculiarity with the former. A cure was wrought by being pinched and connecting the discomfort with the pinch. He did not know of a single case that has been cured by hypnosis alone.

Dr. Sachs believes that imperative concepts are physical phenomena, allied to a physical condition, and do occur in persons otherwise normal; that hyphosis is rather the origin than a method of cure in this condition.

Dr. Putnam thought that the use of hypnotism was curative sometimes in cases of sexual perversion or drug-habit.

Dr. Browning said if a woman who had come of a good family, but whose environments precluded any mental development, could embrace a wider field of cultivation, she could be cured.

In closing, Dr. Angell said that the American men or women are not as impressionable to hypnosis as are the French or German or other Continental races.

Wernicke's Conduction Aphasia, With Autopsy.—Dr. Howell T. Pershing, of Denver, related a case of a man, aged forty-five years, brought into the hospital in an unconscious condition. The history showed that the man had fallen from his wagon into the bed of a small stream. There he lay for thirty-six hours before being discovered. Examination revealed the right arm and leg rigid and tremulous. No sign of injury to the head was apparent; the pulse and heart were normal; respiration 20, somewhat stertorous; temperature 99° F.; urine normal. Conformable syphilitic thrombosis in the left hemisphere. Inunctions and potassium iodide were given. In about a week consciousness returned, but the man's talk was a mere jargon. There was no paralysis. The word-deafness disappeared at the second week and nothing remained but the jargon paraphasia and certain associated defects. His reading was markedly paralexic; acuity of vision was good. Hemianopsia was absent and he kept an observing eye on everything. There was substantially no change until January 23d, when vomiting suddenly appeared and the patient relapsed into unconsciousness. Pulse 64, weak and soft. Heart-sounds normal. Temperature in right axilla, 97.7° F.; in the left 97.2° F. Respiration of the Cheyne-Stokes variety. Unable to swallow. Death occurred January 29th.

A Case of Bullet Wound of the Spinal Cord.—Dr. Joseph Sailer reported the case of a man aged thirty-one years, a major in the Cuban army, who was wounded November 2, 1896, by a ball that entered one cm. to the left and just below the right nipple, passed out about 2.5 cm. to the left of the spinous process of the twelfth dorsal vertebra, penetrating the lung, liver and spinal column. There was marked atrophy of the gluteal region. Three years later a laminectomy was performed to relieve the distressing lancinating pain, and a spinal pachymeningitis was found. Allocheiria was a peculiar symptom of convalescence.

Dr. S. Weir Mitchell said that to him the disappearance of the buttock-muscles was very remarkable.

Dr. Putnam mentioned the case of a woman who had a fall in 1897. The cardinal symptoms were complete paraplegia and loss of sensation of the lower extremities of the trunk with blunted sensation of the arms, but no loss of power in the muscles of the upper extremities. Operation revealed the cervical spine of the sixth vertebra broken and freely movable.

Contribution to the Study of the Plantar Reflex.—Dr. G. L. Walton read a report of seven hundred and fifty tests, made with special reference to the Babinski phenomenon. His conclusions bear out the researches of Babinski, Hurd and Collier.

Tumor of the Superior Parietal Convolution Accurately Localized and Removed by Operation.—This case was of unusual interest from the clinical, physiological and surgical points of view. The medical history of the case was presented by Dr. Mills, the surgical history by Dr. Keen, and a pathological report on the nature of the growth by Dr. William G. Spiller. The patient was a man, fifty-six years of age, who had had some neurasthenic and other symptoms since 1884, but who first began to have paresthetic attacks affecting his right upper extremity in 1894. These attacks were of irregular and infrequent occurrence, and were variously described as ant-like feelings, of crawling, tingling or battery sensa-

tions. After the attacks the arm usually felt somewhat heavy. He frequently complained of a feeling of pressure or discomfort in the head and especially in the left frontoparietal region. Sometimes this feeling was described as a headache, but he never had the typical headache of a case of brain-tumor. Optic neuritis was absent from first to last, and vertigo and vomiting were so infrequent as not to call for special consideration. The patient was frequently hysterical and despondent. About five months previous to the operation the patient began to show some ataxia in the right arm and later in the right leg, and when investigation of his condition was first made by the writer all forms of cutaneous sensibility were impaired, muscular sense was lost, and astereognosis was a marked symptom. As the case progressed paresis and eventually paralysis of the arm and leg supervened, this when complete of course masking the ataxia. The patient developed a disorder of speech chiefly showing itself as a verbal amnesia and fatigue on reading. At one examination the patient showed a temporary partial right hemianopsia. Reversals of the color fields and contractions of the fields for form similar to those supposed to be typical of hysteria were present at several of the examinations. The reflexes on the ataxic and paralyzed side were somewhat exaggerated, ankle-clonus being present. The patient was emotional and markedly hysterical.

An operation which was successfully performed by Dr. W. W. Keen November 24th exposed a tumor in the exact region which had been assigned as the seat of the growth, namely, the superior parietal convolution. As the flap was not to be in the thin squamous portion of the temple, but in the parietal, which might cause great embarrassment from a very thick skull, not only by the time required to chisel through the bone, but the difficulty of fracturing the base of the osteoplastic flap, Dr. Keen first made two trephine-openings, 0.5 cm. in diameter, at the two points between which he wished to fracture the flap. The skull was found, as had been feared, unusually thick, a full centimeter. This being the case a Gigli wire saw was passed between the two points and the bone sawn half through in order to weaken the base of the flap. A large flap, each side of which measured 10 cm. long, was then made, the anterior border of it being a little in front of the fissure of Rolando; the upper border within 1 cm. of the median line.

As soon as the dura was exposed at the lower portion it was suspected that there was fluid beneath it. A dural flap was then cut, with the base upward. The tumor suddenly came into view at the anterior superior angle. It measured 5.5 cm. by 4.5 cm. and weighed one ounce and three drams after removal. It was made up of small granular masses like those of an ordinary raspberry and was of a deep red or purple color. In order to remove the entire tumor a portion of bone was removed by the rongeur forceps anteriorly. The tumor had begun as a subcortical mass and recently burst through the cortex. The tumor, being separated from the brain tissue, was removed and with it a long finger-like cyst which extended, by measurement, 10 cm. (four inches) into the substance of the brain and contained one and a half to two ounces of fluid. The patient made a complete and very smooth recovery, the wound being entirely well by the sixth day. His speech completely returned, the paralysis of the leg and arm largely disappeared, cutaneous sensibility was in time restored, and he was so far recovered that he was able early in March to start for a short trip to Egypt. He reached this country again April 19, and was seen last by Dr. Mills April 24, just one week before the meeting of the Congress. He has regained all the movements of the extremities on the affected side, although he has not full strength in the affected limbs. The muscular sense, especially in the lower extremity, is still somewhat impaired, as would be expected from the tissue lost by the encroachment of the growth.

Dr. Wm. G. Spiller made a careful microscopical investigation of the growth. He classes it as an endothelioma, and believes that it probably originated in the walls of the blood-vessels.

Dr. Dercum said that, having observed the patient personally, he thought too much credit could not be given Dr. Mills for the brilliant and satisfactory result.

Dr. Walton spoke of an elderly man whose symptoms began with tremors in the wrist, followed by paralysis in the arm and leg, the latter being of the spastic variety.

Clinical Study of the Reflexes —Dr. Joseph Collins read this paper. It was desired to ascertain the physiological nature of the tendon-reflex phenomena and to find out their association with muscle tone. The writer concluded that muscle tone and the tendon reflexes were closely associated. In fact that the tendon reflexes were due to muscle tone. The greater the tonicity, as determined by the tonometer, the greater was the tendon reflex.

Dr. S. Weir Mitchell alluded to the reinforcement of knee-jerks with literary references and lauded the work of the American neurologists. Muscle reaction in its different manifestations was likewise discussed.

Dr. Sachs dissented from the view held by Dr. Collins that muscle tone had anything to do with the character of the tendon reflex. That they might depend on some other common factor could not be denied.

Dr. Knapp and Dr. Spiller spoke in the closing part of the discussion.

Second Day—May 2d.

Adiposis Dolorosa —Dr. F. X. Dercum read this paper and presented microscopical findings. The patient was a woman, fifty-one years of age, a native of Ireland. Family history revealed nothing abnormal. She was well until forty-nine years of age. Alcoholic excess was noted. En-

largement of the arms, and shooting pains in both shoulders, the side and chest, most marked in the upper arms, were primary symptoms. No thickening of the skin nor was it adherent to surrounding tissues. Swelling did not involve the muscles. Quantitative and qualitative changes in the muscles and forearms, while there was diminution of cutaneous sensibility. There was loss of knee-jerks, but no alteration of gait. The face was pale and likewise the mucous membrane. The skin was dry; the mind was not affected, and the hair was dark and fine. Examination of the eyes showed retraction of the visual field. Test of urine and blood negative; no leucocytosis. For eleven years the patient was under observation. There were nodules present, and the abdomen, hips, thighs, and legs below the knee were noticeably enlarged. Involvement of feet and hands came last. Vomiting, often containing blood, would come after severe attacks of pain; spells of dyspnea and bronchitis accompanied her symptoms. Cardiac trouble was present, which ultimately resulted in death—fatty degeneration of the heart—in connection with adiposis dolorosa. At the necropsy, there was no hair on the pubes nor in the axilla; the intestines were distended with gas, but with the exception of fatty infiltration there was nothing abnormal. Microscopic examination revealed nothing of importance, but the muscle of the heart was found to be very friable and of yellowish color, with marked change in the muscle itself. The subcutaneous tissues, spinal cord, peripheral nerves, thyroid gland and pituitary body were all examined. The nerve-fibers were atrophic and markedly diminished. In the dorsal and cervical regions of the spinal cord there were present certain changes. Neither the brain or pituitary body presented any alteration. While the thyroid gland was not weighed, it was found to be abnormally small. There was no colloid material. A theory presented was that the thyroid gland being deranged, certain abnormal substances were brought into the circulation

Dr. Burrin in discussion said that he had made an autopsy and examined a case of the same character, with a new growth of the pituitary body. This was purely accidental, as a diseased pituitary body in his opinion would not cause deposits of fat. In his case the thyroid was undoubtedly affected with an interstitial neuritis within the muscles. Some of the voluntary muscles-fibers were also degenerated.

Dr. Putnam referred to a patient with progressive muscular dystrophy and congenital blindness which happened in the same family.

Anatomico-Cytological Relationship of the Neurone to Disease of the Nervous System.—A discussion on the neurone theory was opened by Dr. L. F. Barker. He referred to the units in the nervous system and the neurone theory was dealt with historically. In 1891 Waldeyer collated evidence supporting the view and gave to the nerve-units the name "neurones." The neurone doctrine presented nothing more than the cell doctrine applied to the nervous system, until it was proved that the integral parts of a single cell are the axis-cylinder of a nerve-fiber and its end ramifications; before this it was impossible to apply the cell doctrine intelligently to the nervous system. The theory of contact is not an integral part of the doctrine of nerve-units or neurones, and as to the retraction theory it has never had any adequate basis. "The studies of Apathy and Bethe are regarded as extremely important as bearing on the intimate relations which exist between the nerve-centers, they do not interfere in any way with the retention of the units themselves."

The Pathologieal Changes in the Neurone.—Dr. W. G. Spiller then presented the pathological side of the problem. His propositions were: Is the neurone affected by disease, that is, can the cell-body become diseased and die without the existence of the axone? Does the disease of sensory neurones affect the motor neurones? A neurone becomes diseased to what degree? Should an axone be cut, there would be alteration and perhaps death to the cell-body in which the axone arises. It was further proposed that an axone is only partially dependent on the nerve-cells for vitality. As soon as there is a cut-off of the blood-supply the portion deprived of circulation will die. Radiographs were shown of certain pathological changes in the brain. He found alteration of the nerve-cells in a removed Gasserian ganglion, but in the sensory tract there was no change. The entire neurone has a tendency to undergo alteration when it becomes injured or diseased.

The Neurone Doctrine and Therapeutics.—Dr. B. Sachs took up this important subject in the discussion. There is promise of a general revolution in the conception of nervous disease by the advent of the neurone theory. There is still a question whether it has been beneficial in defining the causation and development of certain diseases of the nervous system. The nervous system is a series of contiguous, not continuous, units; in this nerve-unit, composed of the cell-body, with its dendrites, the nerve-fiber or neuraxon and the terminal tufts, the cell-bodies produce a trophic influence over the entire neurone. Before we could appreciate the value of the neurone, the trophic influence of the cell-body in its relation to the nervous system had to be discussed. Tabes dorsalis is a disease of the direct sensory neurone. The sensory fiber is the seat primarily affected whatever the poison may be that is circulating in the body. The ganglion-cell would not be diseased unless there was something wrong with the peripheral stimuli conveyed to it. Sachs thought that the time had not yet come when the doctrine could give us clear-cut ideas as to therapy.

The Physiological Significance of the Size and Shape of the Neurone.—Dr. H. H. Donaldson presented interesting data regarding the study of the neuronic elements in the white rat. In these animals the examination of the cell-bodies from the spinal ganglion was made. The ganglionic cells become progressively larger. The sciatic nerve of

the white rat at birth does not contain a medullated fiber; there are no medullated fibers, central or peripheral. The medullary sheaths begin to appear during the first six or eight days, and their appearance about the axones in the first case is a very rapid process.

In Dr. Putnam's opinion the idea that the cell-body is the receptacle for the storage of anything particularly standing for the function of the nervous system as a whole should be abandoned. He thought the term is very often used "in books on clinical medicine of the storage of memories of the cortex in the brain."

It seemed to Dr. Longdon that to start now to criticise the neurone doctrine and neurone discovery or hypothesis is very much like criticising the architecture of a building of which the plans are not yet drawn. He was of the opinion that in regard to the neurone doctrine, anatomically it was of great assistance.

In the opinion of Dr. Van Gieson the neurone theory needed no defense.

The term neurone in the opinion of Dr. Mills had done harm rather than good in the teaching of the new doctrine in this way, but he thought there could be no doubt that the neurone theory must stand, there has been demonstrated a certain degree of interdependence of nerve-cells.

Dr. Dercum thought it was best to wait until there was more complete knowledge on the subject, until the details of the relationship of the neurones to each other had been ascertained.

With the neurone doctrine, Dr. Collins said, the profession is dealing with facts, not theories. A valuable point brought out was the necessity of using the nerve-cell as represented by the neurone and not speaking of the nerve-cell as meaning the cell-body. In the future this would be productive of good results.

The pathological, physiological and anatomical relationship of the neurone theory were gone over by Drs. Thomas, Smith and Angell.

Dr. Sachs, in closing, said he did not want to be understood as being pessimistic; he was simply anxious; even in the neurone theory there is some limitation.

Dr. Barker's conception of the neurone was not purely morphological; it is based just as much on physiological and pathological results as on morphological. There is a tendency to make too great a distinction between the morphological and physiological concepts.

Third Day—May 3d.

Clinical and Anatomical Analysis of Cases of Diffuse Myelitis.—Dr. James J. Putnam's case of pernicious anemia was very manifest. The doctor did not think that it was the result of accidental vascular lesions, but that it is a distinct disease with clinical and anatomical characteristics. There was, in this case, numbness of the extremities, with cachexia, ending with softening of the cord. The lesions occur in the foci; the nerve-root zone is unaffected, and the lesions are referable alone to the spinal cord. The indications of anemia are very common, and in these cases they are universally present. In his second case of pernicious anemia, there was great improvement in the blood, the blood-count having reached 5,000,000, where previously it was but 3,000,000. However, there was a continuation of the spinal symptoms.

Dr. Langdon, in discussion, said that two groups of pernicious anemia were to be noted; one did not have spinal degeneration. He had followed two cases of marked pernicious anemia and had tested them but a short time before death, and there was not any evidence of spinal symptoms. There was in his own practice a woman who had a spleen which reached as far as Poupart's ligament and to three inches to the right of the umbilicus. There was no appreciable functional alteration upon careful examination, while her nervous symptoms were exceedingly dense. This patient presented likewise an anemic appearance. In the first case of pernicious anemia the patient had mucous colitis; it was interesting to note the association between the state of degeneration and the condition of the blood.

Brachial Plexus Neuritis.—Dr. Morton Prince reported a case of section of the posterior spinal roots for relief of pain in a case of neuritis of the brachial plexus; in which there was cessation of pain in the affected region, and later the development of Brown-Séquard paralysis in the area and pain in other areas as result of laminectomy in a man who received a Colles' fracture of the left wrist and paralysis of the right arm by being struck by a train. The paralysis affected the muscles of the forearm and pronators, rendering the arm useless from the shoulder down. There was pain in the forefinger, back of the wrist and also in the thumb, while sensation over the lateral areas was diminished. Operation was undertaken for the relief of intense pain, but it was not performed on strictly neurological principles. Another operation, however, was successful for the purposes for which it was performed. Before the operation and a little over a month after the accident, there were areas of anesthesia and analgesia over the radial aspect of the hand, thumb and forefinger, which extended upward over the same aspect of the arm. Subsequently severe pain developed in the back of the neck and this, it was thought, might possibly have been caused by injury to a nerve at the operation. The patient could not support himself and his leg was spastic. In the right foot, there was extreme coldness. The patient is very anxious to have his arm amputated, as it is paralyzed from the shoulder down, and this has been promised. The date of the operation was October 20th, the injury having taken place about fifteen months or a year and a half before. Dr. Prince further said that there was extreme atrophy of the muscles, especially of the deltoid. The cause of the present pain about the shoulder-joint is due to the fact that the muscles of the shoulder-joint and of the arm hang down and drag on the shoulder.

In discussion, Dr. Meyer expressed the opinion that physicians were again considerably at sea as to the clinical and anatomical corollations of the Brown-Séquard paralysis, inasmuch as Brown-Séquard, in his last work, said that he was obliged to reverse his view concerning the subject, since on cutting the posterior root he had obtained the Brown-Séquard symptoms complex, and that when making a second hemisection lower down, after the Brown-Séquard symptoms had been produced, he was able to reverse the whole picture in the posterior segments of the body. It was a question whether the Brown-Séquard paralysis was the product of a blood-clot. Dr. Prince had never seen a laminectomy performed for any purpose of this kind without feeling that there is some possible danger of the production of a blood-clot.

Revised Interpretation of the Central Fissures of the Educated Suicide's Brain Exhibited to the Association in 1894.—Dr. Wilder presented charts and drawings of the brain of a suicide, who, previous to his death, had, in writing, willed his brain to Dr. Wilder. Shortly after he killed himself by a pistol-ball. The first ball striking about the middle of the forehead was deflected and did not result in death. He shot himself fatally, however, in the right temple. The striking point was his persistency to end his own life. The case was of exceeding interest, not only from a medico-legal standpoint, but also from an anatomical one in relation to the location of the fissures of the brain. Dr. Wilder went over the topography of the encephalon and gave his reasons for change of view of his interpretation of the central fissures.

Dr. Meyer said, in speaking of the interpretation of the fissures of the brain, that at times we often fail to find Betz's cells, while in certain parts of the paracentral lobule down to the corpus callosum Betz's cells are found.

Dr. Charles K. Mills gave a note of warning in reference to arriving too quickly at conclusions with regard to the duplication of fissures; he had seen a great many brains in the last twenty years, and he had seen an appearance of the duplication of the central fissure, although not as marked as in Dr. Wilder's case. The conclusion ought not to be arrived at that duplication of the main fissure like the central fissure was present, until other possibilities are excluded.

Malaria Presenting the Symptoms of Multiple Sclerosis.—Dr. William G. Spiller read this paper. The patient was a sailor and it was thought that he was not likely to be exposed to malaria. His health was good until he had a chancre in 1890. Two years later he lost power in the right side of his body. It returned a month subsequently. In 1895 he complained of headaches, vertigo, and a feeling of drowsiness. In the same year there was loss of power in the left side of the body, but from this he recovered. He stood unsteadily when resting on the right foot, and could not stand alone on the left foot on account of ataxia. Death came in September, 1899. At the autopsy an enlarged spleen was observed. The diarrhea, which had been severe before death, was thought to be malarial in character. There was an unmistakable, but moderate, sclerotic condition of the cord, but no degeneration of the spinal cord. There were hemorrhages in the brain and symptoms of disseminated sclerosis. There was intention tremor.

Dr. Mills said that he would not attribute the symptoms in a case like this necessarily to toxemia, but would rather consider the possibility of small hemorrhagic foci as the cause of symptoms.

The idea of malarial toxemia causing the symptoms described by the author is rather startling, but not, it must be confessed, beyond the realm of possibility.

Multiple Sclerosis With Autopsy.—Dr. Charles W. Burr and Dr. McCarthy described the case of an electrical engineer. The autopsy showed big patches of sclerosis affecting the spinal cord. The optic nerve was greatly degenerated, and in the acute patches there was extreme proliferation of the connective tissue surrounding the blood-vessels.

A Few Reconstructions of Parts of the Nervous System.—Dr. Adolf Meyer presented pathological specimens of white rats. He believed that the plates he used were less fragile than the wax plates. Dr. Charles K. Mills thought they were very good in teaching the structures and the organ. He thought, that by this method, the teacher could readily point out and the student comprehend the parts very quickly.

Two Cases of Tumor of the Spinal Cord.—These were reported by John Jenks Thomas. The first case referred to was a woman, twenty-one years of age. There was sensory and motor paralysis and likewise paralysis of the sphincter. There seemed to be no pain, and the patient apparently remained in the same condition for thirteen years, except for an outbreak of mental trouble, from which she recovered. Death resulted from exhaustion, bed-sores, diffuse nephritis and chronic cystitis. There was observed at the necropsy a tumor of the dura, in the mid-dorsal region, which had completely compressed the cords beneath it. The tumor was composed of cells which were endothelial in character. The cords showed a destruction of nervous structure, which was replaced by overgrowths of neuroglia. In the second case there was an intra-medullary glioma in the cervical regions, in a boy of six years. The symptoms developed after a slight injury, beginning with pain in the right hand and arm, the left forearm being congenitally absent. There was pain in the shoulder and rotation of the head to the left. After death the autopsy showed a glioma of the whole of the cervical enlargement of the cord, with hemorrhage. On microscopic examination it was found that the tumor was a cellular growth. Sudden death came from hemorrhage into the tumor. The case was unusual because of the rapid course from the time of the first development of the symptoms, and because of the youth of the patient.

REVIEWS.

Lehrbuch der klinischen Hydrotherapie für Studierende und Aerzte. Von Dr. Max Matthes, a. o. Professor und Direktor der medizinischen Poliklinik an der Universität Jena. Gustav Fischer, Jena.

The author here presents in typical German fashion a text-book on hydrotherapy founded on a number of years' experience in practical demonstration and lecturing to the general practitioner in Stintzing's clinic at Jena. At the present time hydrotherapy needs no special apostle; its merits are acknowledged by most, and would be by all, were it not for the eccentricities of some of its devotees.

In the present volume the subject matter is discussed under three heads: General Considerations, Technic of Hydrotherapy and Special Hydrotherapy. The first portion is especially thorough and valuable, analyzing as it does the influences of heat and cold on the different tissues of the body. The technic of baths, packs, douches, etc., etc., is systematically treated and the small details of application carefully expounded. The portion on special treatment is, from a practical point of view, very valuable. Here the application of hydrotherapeutic procedures to disorder and disease of the different organs is especially extensive and the specialist, as well as the general practitioner, can derive much benefit therefrom.

The work is not over large, is well written, the illustrations are ample, although not many, and the systematic mode of treatment is exemplary.

Elements of Clinical Bacteriology. For Physicians and Students. By Dr. Ernst Levy, Professor in the University of Strasburg, and Dr Felix Klemperer, Privat Docent in the University of Strasburg. Second Edition, Revised and Enlarged. Authorized Translation by Augustus A. Eshner, M.D. W. B. Saunders, Philadelphia, 1900.

This book represents, according to its authors, an attempt to group the result of bacteriologic investigation from the clinical point of view. Needless to say, in such good hands the object attempted has been successfully attained. Few manuals will give the general practitioner a more practical, or at the same time a more thoroughly scientific idea of the points where modern bacteriology touches clinical medicine. The subjects in which this second edition has been improved and enlarged serve to bring out very fully the practical character of the work. Recent observations with reference to varieties of the diphtheria bacillus and the pseudodiphtheria bacillus and their occurrence in healthy throats are especially brought out. The tendency of the pneumococcus to produce other lesions besides characteristic inflammation of the lung and especially its occurrence in skin-abscesses and phlegmonous processes is insisted on. The chapter on botulism gives a good review of what is known at present of the bacteriology of poisoning by meats. Recent work on the tetanus bacillus and its toxins and the effect of antitoxin make another modern feature of the book.

The translation has been very well done and the American edition has been distinctly improved by the addition of illustrations.

The American Year-Book of Medicine and Surgery. Edited by George M. Gould, M.D. Volume II. Surgery. W. B. Saunders, Philadelphia, 1900.

The volume of the year-book relating to medicine was reviewed some time ago. The present volume contains an excellent review of the surgery of last year. We are glad to note that the abstracts from the literature of surgery are more nearly up to date than is the case in the medical volume. References in this are as late as November so that the progress for the year is very fairly represented.

The collection of the statistics of operations for the radical cure of hernia shows how much improvement has taken place of recent years bearing on the safety of such operations. In the hands of skilled operators the mortality of these operations is now probably less than one per cent. in uncomplicated cases.

In addition to surgery the present volume includes obstetrics. It is interesting to note that all of the recent literature condemns vaginal douching before labor, unless there already exists a distinctly purulent discharge or some intra-uterine manipulations are to be performed. There seems to be almost a consensus of opinion that when labor-pains are severe the administration of an anesthetic, especially of chloroform, shortens the duration of the labor, spares the woman fatigue and exhaustion, adds to the effectiveness of uterine contractions, quickens the progress of labor and prevents shock.

In the subjects treated in this volume the year-book is a very practical reflection of the progress of medicine and is calculated to be of great service to the busy practitioner.

Diseases of the Genito-Urinary System. By Eugene Fuller, M.D., Professor of Genito-Urinary and Venereal Diseases in the New York Post-Graduate Medical School, etc. The Macmillan Company, New York, 1900.

In the preface of this book Dr. Fuller states that, although there are a number of works on genito-urinary diseases, nearly all of them have either not been written by a single hand or have been written from a purely venereal, or dermatological, rather than from a surgical standpoint. The present work is intended, then, to be a mirror of genito-urinary practice from the standpoint of the surgical specialist in venereal diseases. This object is very commendably accomplished. The tendency generally in the book is not to give many and sometimes contradictory opinions, but to state simply the author's practice in the treatment of venereal affections. Certain chapters deserve special commendation. As

might be expected, the review of the subject of seminal vesiculitis is very well done. To Dr. Fuller is due much of our present knowledge of the affections of the seminal vesicles and their treatment. A very practical idea of what symptoms are caused by affections of these organs and how much can be done for their relief is given in a concise and very practical way. The chapter on the hypertrophy of the prostate and its treatment contains a full review of the present status of prostatic surgery. A very good idea of what may be accomplished for prostatic symptoms by palliative treatment is also given. For the radical treatment by removal of the prostate the author's own method is recommended. He removes the enlarged gland from within the bladder after a suprapubic incision and an incision through the base of the bladder with specially-constructed, serrated scissors.

The chapter on sexual neuroses receives a much more conservative treatment than might be expected at the hands of a professed surgeon. Dr. Fuller does not believe that these neuroses often depend on some nearby focus of disease which can be removed by surgical interference. While this is sometimes the case, too many surgical operations have been done on the strength of supposed reflexes that really never existed. On the whole, Dr. Fuller's book is a most satisfactory work on a difficult specialty, the constantly varying aspects of which require frequent consultation of the latest authorities.

Imperative Surgery. By Howard Lilienthal, M.D., Attending Surgeon to Mount Sinai Hospital. New York: The Macmillan Company, 1900. $4.00.

The appearance of a book on surgery with so novel a title is in itself bound to attract attention, and, if it be further said that the treatment of the subject is equally original and novel, a wide publicity of this merited work ought to be its lot; for it is quite a relief to read a book on surgery, selected from the maelstrom of surgeries now in the book-mart, the author of which has succeeded in tearing himself away from their mimicked conventionalities and who tells his readers a live surgery born of the school of exigencies and free from flourishes.

To paraphrase the preface, the *raison d'être* for this work is to reach those of the profession who have indulged in long distance surgery, but who are called upon in emergency to execute an operation at short range. This book ought, therefore, to find most favor with the hard-pressed, extra-urban physicians, which class collectively is engaged in doing the "greatest good to the greatest number." To the surgical neophyte entering on his term as hospital interne and to the enterprising hospital graduate this is an inestimable book of reference. It should not be implied that this "Imperative Surgery" is a "First Aid to the Injured." It is more than an emergency surgery, since it treats of conditions calling for some deliberation before operation. So concise, unequivocal and straightforward is the style that it inspires confidence to follow the advice. The directions are very practical, yet free from empiricism, and theoretical arguments appear only to elucidate diagnosis or technic.

The illustrations, very vivid photographic reproductions and some few drawings, are all original and harmonize with the text. In this connection two omissions occur to us; one is an illustration of the localization of the cortical centers, the other is a diagrammatic chart of the elective points of ligation of vessels.

There might be occasion for discussion on points in themselves mooted, but which do not impair the validity of this "Imperative Surgery," *de facto* an excellent clinical surgery.

In conclusion, the publishers deserve commendation for the artistic make-up of the book, which is printed in large type on heavy, sized paper, with a wide margin.

BOOKS RECEIVED.

The Medical News *acknowledges the receipt of the following new publications. Reviews of those possessing special interest for the readers of the* Medical News *will shortly appear.*

Transactions of the American Dermatological Association. Twenty-third Annual Meeting. Held in the College of Physicians, May 30-June 1, 1899. G. T. Jackson, M.D., Secretary. The Rumford Press, Concord, N. H. 1900.

Essentials of Diagnosis. By Drs. S. Solis-Cohen and A. A. Eshner. Saunders' Question Compends, No. 17. Second Edition. Revised and Enlarged. Illustrated. 418 pages. W. B. Saunders, Philadelphia. $1.00.

A Handbook for Nurses. By Dr. J. K. Watson. American Edition. Dr. A. A. Stevens. Demi 8vo., 413 pages. W. B. Saunders, Philadelphia. $1.50.

The Pathology and Surgical Treatment of Tumors. By Dr. N. Senn. Second Edition. Revised. 8vo., 718 pages. Illustrated. W. B. Saunders, Philadelphia. $5.00.

The Medical Diseases of Childhood. By Dr. Nathan Oppenheim. 8vo., 653 pages. Illustrated. The Macmillan Company, New York and London.

Transactions of the Twenty-first Annual Meeting of the American Laryngological Association. Held in the City of Chicago, Ill.

Manuel Complet de Gynécologie Médicale et Chirurgicale. Par Dr. A. Lutand. 8vo., 712 pages. Illustrated. A. Maloine, Paris.

Diseases of the Gall-Bladder and Bile-Ducts, Including Gall-Stones. By Dr. A. W. Mayo Robson, assisted by Farquhar Macrae. Second Edition. 8vo., 313 pages. Illustrated. William Wood & Company, New York.

Lehrbuch der klinischen Hydrotherapie. Für Studierende und Aerzte, von Dr. Max Matthes. 8vo., 415 pages. Illustrated. Gustav Fischer, Jena. Eight marks.

Chemistry and Physics. A Manual for Students and Practitioners. By Drs. W. Martin and W. H. Rockwell. 8vo., 374 pages. Illustrated. Lea Brothers & Co., Philadelphia and New York. $1.50.

ORIGINAL ARTICLES.

TREATMENT OF MEMBRANOUS COLITIS.[1]

BY W. H. THOMSON, M.D.,
OF NEW YORK;
PHYSICIAN TO ROOSEVELT HOSPITAL.

IT is to be hoped that but few physicians will be called upon to treat a case of membranous colitis at the outset of their career, for if so they will be apt to think that they have made a serious mistake in the choice of their life-calling. The sanguine expectations with which they left college that success in practice is sure to follow good training and earnest endeavor are likely to be disappointed in every particular and in the most trying fashion whenever a patient comes with a story of a chronic habit of passing long shreds or membranous casts of the bowel.

The experienced clinician has learned to note early in eyes and forehead signs of head trouble, and about the nostrils and the upper lip signs of thoracic derangement, but when the corners of the mouth go down in woebegone expression he knows that inward grief reigns somewhere in the abdomen. But of all physiognomies a case of membranous colitis wears the most settled aspect of confirmed wretchedness, which the young physician, confident in his resources, meets with assurances of coming relief. But his subsequent experience is apt to be much as follows: For some days his remedies seem to be working well. Then the old pains in the bowels return, now with a sense of general distress pervading the abdominal cavity, best described by the colored woman's term, "misery." Then follows a more localized pain, either griping or cutting or sickening, which is explained as due to wind, for often various rumblings precede or accompany it. The abdominal parietes frequently become very tender to palpation in places, but no dependence can be placed upon such local signs, for, at the next visit they are somewhere else, although as bad as ever. Meanwhile the patient develops a decidedly varied train of nervous symptoms. The mind refuses to think or to do anything but feel conscious of distress. Unbearable headaches, neuralgias and pains here and there, palpitation, sinking spells and weepings make up the story, until, finally, the bowels with exhausting pains empty themselves of quantities of long strings or strands of mucous masses, mixed with the feces or following them, sometimes with a few streaks of blood and rarely with a small amount of pus. Then, for a while there is comparative quiet, but sooner or later, the old story is repeated with every accompanying variety of dyspeptic symptoms, referred now to the stomach and now lower down, and each time explained by this or that offence in diet, by the late bad weather, or something of that character.

In no other complaint is the morbid self-consciousness characteristic of abdominal affections more marked. The patient can neither think nor talk about any other subject than his many woes. Therefore, by reason of the great frequency, as well as variety of the accompanying nervous symptoms, many writers have been led to regard the disease as primarily a neurosis, or, at least, to speak of a nervous colitis. I regard this view of its pathology as analogous to that of the philosopher who admired the wisdom of the Creator in causing large rivers to flow past large towns. A colon, the lining of which has fallen into the condition which such a secretion indicates, presents wide tracts of surface for the absorption of all kinds of excrementitious poisons into the blood. It is these poisons, which, circulating everywhere where there are nerves, produce all the symptoms referable both to the splanchnic and to the cerebrospinal tracts, which make up the multiform nervous features of the case, and offer a sufficient explanation of them without needing the intervention of any vague primary nervous lesion.

Moreover, while nervous lesions or irritations do sometimes produce trophic changes, nevertheless no instance can be cited of chronic fluxes from mucous membranes having any such origin. Chronic bronchorrhea and chronic gleet certainly are never primarily neuroses, although asthmatic spasm may complicate the one or an irritable stricture the other. The truth is that, while in membranous colitis the patient may be reduced to a state of pitiable emotional weakness, the objection to the view that this indicates a nervous etiology is that it leads us in a wholly wrong direction when the subject of treatment comes into consideration. How independent of any antecedents of a neurotic kind this affection may be is illustrated by the following case:

Dr. H. A., a middle-aged physician in active practice, had always enjoyed excellent health until he accepted a staff appointment in the volunteer service during the late Spanish War. While on cavalry duty at a camp in Virginia, which required his being for hours in the saddle, in July, 1898, he began to suffer from an intense irritation referred to the rectum. This measurably subsided for a time, but returned in November and steadily grew worse during the following winter. He then had his sphincter stretched

[1] Read before the Section on Medicine of the New York Academy of Medicine, February 20, 1900.

by a rectal specialist, but with no benefit. His symptoms were recurrent attacks of severe tenesmus which tormented him, especially at night, preventing sleep, and which were accompanied by discharges of large quantities of mucus. He lost forty pounds in weight and was obliged to give up practice. He came to me for treatment in May, 1899. Examination showed the rectal mucous membrane to be deeply congested, but there were no signs of ulceration. After six weeks of recourse to remedial measures, which will be mentioned later, he was relieved of his urgent symptoms, so that he regained his weight and was enabled to resume practice, but every now and then, he has had temporary relapses and has passed complete casts of the bowel of greater or less length. These in turn ceased, but in January, 1900, he reported another return of tenesmus and reappearance of the membranous casts. He has again improved, and I have hopes that like many other cases his relapses will grow fewer and at last cease altogether. But what I would note here is that, although he began to develop all the train of nervous symptoms above referred to, there can be no doubt that none of them had any primary relationship to his trouble, but were purely secondary. The beginning of the disease was clearly due to a local irritation excited by local causes, acting first on the lower end of the intestinal tract, and gradually extending upward. In like manner, one of the worst cases for nervous complications which I have met was in a young married woman who dated her disorder from prolonged riding in the country on a bicycle.

Now, what does pathological anatomy reveal as to the nature of this disease? Unfortunately, it must be admitted that autopsies show us more what this intestinal disorder is not, rather than what it is. Thus, with beginners, it is very natural to surmise that extensive tracts of ulceration will be found in the colon. But generally nothing of the kind is discovered, although the morbid process has continued severely for months and years until the patient succumbs to it. Instead the colon is found considerably dilated, its walls thin and atrophied, with here and there patches of simple congestion, toward the lower end clumps of small, thin veins, not collected into polypi nor resembling hemorrhoids, are found, and evidently these are the source of the bright red blood which is often mixed with the mucous discharges, but even they do not show that their coats have been opened by an ulcerative process. Microscopic examination of the discharged membranes themselves shows nothing but a structureless material which is albuminous in composition, but containing no fibrin even in the most consistent patches, and in typical samples wholly devoid of pus, or leucocytes, or of other ingredients of inflammatory exudates, the cells present evidently being the epithelial cells of the large intestine which have undergone fatty degeneration.

The clinical symptoms also are quite unlike those of ulcerative colitis, for obstinate constipation, as a rule, both precedes and accompanies membranous colitis, while diarrhea as uniformly accompanies ulcerative colitis.

There are several forms of secondary membranous colitis, on the other hand, which have nothing in common, excepting the formation of membranous patches, with the disease which we are considering, either in their etiological or in their clinical characters. Thus, in some cases of chronic Bright's disease, the patients lie comatose for days and pass loose movements in bed. After death the colon, as well as parts of the small intestine, are found lined with thick, diphtheritic-looking patches, while, because such membranous exudations never appeared in the dejecta, their existence was demonstrated only on the post-mortem table. On the other hand, the presence of both albuminuria and of hematuria is not uncommon, as temporary symptoms in true membranous colitis. In two patients of mine I have noticed these signs of direct irritation of the kidney repeatedly, but I do not place much store upon them, for other signs of progressive renal disease have remained absent, although these patients have been under my continuous observation for several years. I ascribed these renal symptoms to the entrance of the bacillus coli into the blood through the diseased intestinal wall.

A case of true membranous colitis, such as we have been considering, has no real resemblance to a catarrhal colitis or to a catarrhal inflammation of any kind. What leads to a confusion between this especial affection and others, the seat of which is in the large intestine, is the presence, more or less common to them all, of colonic symptoms. Just as any form of arthritis, whether traumatic, rheumatic, gouty, gonorrheal, pyemic, etc., will cause very similar symptoms of pain on movement of the joints, with redness, swelling, etc., so that the most diverse varieties of arthritis can be confounded in diagnosis and even in nomenclature—witness that impossible hybrid, rheumatic gout—so every serious process in the colon will occasion abdominal distress, tenesmus, or "bearing down," or pain before and during defecation, etc., and it is only when we have set these colonic symptoms aside and direct our attention to the conditions which they present, as separately characteristic of each form, that it becomes plain that in true membranous colitis we have a specific affection of the large intestine, the pathology of which is undoubtedly distinct from all other colonic disorders, with, in all probability, as specific an etiology.

From the clinical side some of the etiological factors appear to be direct mechanical irritation of the rectum, as by horseback or bicycle-riding, as already mentioned in two of my cases. Similar to these are cases traceable to pressure on the rectum by uterine fibroids, and it is well to examine carefully in women for the presence of such possible causes. In my opinion, however, by far the commonest cause is the prolonged retention of hardened scybala. A history of pre-

ceding habitual constipation of years' standing is the rule in these patients, and, hence, the greater frequency of the complaint in women. It is striking to find, when we carefully investigate the antecedents of most of these female patients, how evidently they have been subject to fecal retention for months at a time, and there is nothing which favors the formation of stationary hard lumps of feces in the weakened and distensible colon as the habitual use of certain laxatives and cathartics. One of the largest masses of the kind which I have ever had to deal with proved on examination to consist mainly of fig-seeds. Once that this irritation awakens the morbid process in the colon, it seems to change the nutrition of the intestinal wall in its own special way, with a definite tendency for this initial local change to spread in the wall either upward or downward, according to its first seat and, finally, to induce a permanent perverted secretion, which becomes very difficult to alter or to cure.

As to treatment, the first indications are to relieve the colonic symptoms proper, as they may be termed, that is, symptoms which are more or less common to all diseases of the colon, as pain and stiffness of the joints on movement are common to all varieties of arthritis. Thus, nothing is so soothing to the tenesmus, the cutting and bearing-down pains, and the general abdominal distress, as free irrigation of the colon with normal saline solution, to which may be added oil of peppermint, five drops to the pint. Three to five gallons, at a temperature of 100° F., may be employed once in twelve hours, and given by Kemp's rectal irrigator, according to the printed directions which are furnished with this simple and serviceable instrument. The relief which this hot douche affords is often described by the patients as very great, and as enabling them to sleep at night better than any other measure. Care must be taken, however, that all the fluid is returned, lest any quantity retained may afterward provoke a return of pain, thus causing it to act as an enema. By a little practice, however, this may be avoided. Great quantities of mucus are thus dislodged and washed away, but it frequently happens that after the irrigation has been employed, the patient subsequently has a painless movement which consist of a large amount of simple mucus without shreds or membrane. Sometimes I have found benefit from using at the end of the irrigation a gallon of the water in which from 60 to 100 grains of resorcin has been dissolved, being careful that it is all expelled afterward. Once a week a pint of clean, hot water with 30 to 40 grains of silver nitrate may be used instead of the resorcin. Unfortunately, this irrigation is not curative, as it is in many cases of chronic catarrhal or chronical ulcerative colitis, for, although it serves the valuable service of eliminating the complication of direct colonic irritation which so often undermines the patient's health and, by so much, aggravates the local processes of the disease, yet it does not deal with the nutritive change itself in the intestinal wall, but only with some of its effects. Nevertheless, it should not be omitted from the system of measures which should be adopted for the more or less prolonged methods of treatment needful in every essentially chronic disease.

The next question is, Have we any medicinal remedies which can be expected to be of service in changing the disordered nutrition of the intestinal mucous membrane? I believe that we have one such remedy and that is small, and, what I may call alterative, doses of castor oil. I have had patients report that the relief afforded by this medicine has been most unmistakable from its first administration. I prescribe it in an emulsion, of which each tablespoonful contains from one-half to one dram of the oil, preferably one-half at first, to be taken either half an hour before meals or an hour after meals. This should be continued for months together, and only intermitted when it seems unmistakably to increase the patient's dyspeptic symptoms.

The nitrate of silver in quarter-grain doses, combined in pill or capsule form with nine grains of turpentine resin, and taken three times a day, is sometimes of much service, although not as uniformly as in chronic catarrhal or ulcerative colitis, in which complaints a quarter of a grain of opium is added. To enable the turpentine to dissolve and not pass the bowels unchanged, it should be pulverized well with licorice powder and a drop or so of liquor potassæ added to each capsule. After the silver has been taken for six weeks, the sulphate of copper in quarter-grain doses can be substituted for it.

Meantime, membranous colitis is a complaint particularly characterized by general disturbance of the digestive functions of the whole elimentary tract. This is a result and not, as many deem it, a cause of the colitis; but there can be no doubt that the consequent maldigestion and fermentation of the ingesta become of themselves a complication of the original complaint. The stomach is apt to be dilated and the small intestine the seat of disturbed innervation and a perverted secretion. Five grains of resorcin in solution with tincture nucis vomicæ, half an hour after meals, constitutes a good prescription for the gastric symptoms, to be supplemented by ten grains of sodium benzoate and ten grains of bismuth salicylate in capsules, an hour after each meal, as intestinal antiseptics. We should, however, from the first bear in mind the probable dependence of the disease itself on chronic constipation, and against this I would limit myself to the employment of salines exclusively. From one to two drams of phosphate of soda with ten grains of salicylate of soda should be given every morning in a tumblerful of water as hot as the patient can sip it. After a time, the same quantities of sulphate of magnesium may be substituted. Daily massage of the bowels, particularly of the tract of the colon, is also to be highly recommended. We need not fear arousing any inflammatory process by such manipulation, for we are not

dealing with inflammatory disease. Once in a while, however, we do find a region which always remains tender to palpation and in such cases a local blister often is beneficial.

The diet of such patients is important to consider, if only from the fact that many of them most unwarrantably reduce it from fear of this or that article disagreeing with them, according to their remembrance of some severe attack after they partook of it, until they finally live on only some very few and insufficient forms of food. We may simply exclude beans, corn, spinach, and the woody vegetables, along with oatmeal among the cereals, and then encourage the patients to eat meat, poultry, eggs, zoolak or kumyss, peptonized milk and most cereals, with instructions not to care what will happen. In some cases pancreatic emulsion is of marked service.

Finally, bodily movement and out-of-door exercise is beneficial on general principles. Repeatedly, we find a summer change to the country do more good than anything else, for fresh air is the best remedy for constipation that can be named, and its effect is not lost in disease.

Recent writers, notably Hale White, have recommended whenever everything else fails, to give the colon a prolonged rest by the establishment of an artificial anus in the right flank. Some recoveries have been reported from this procedure and I see no reason why in otherwise hopeless cases, it should not be tried.

THE SANITARIUM TREATMENT OF INCIPIENT PULMONARY TUBERCULOSIS AND ITS RESULTS.

By E. L. TRUDEAU, M. D., M.Sc.,
of Saranac Lake, N. Y.

Many years ago circumstances placed me in a position where the problems connected with tuberculosis were of necessity daily before me and afforded ample opportunities for the study of the disease in its clinical, scientific, and humanitarian aspects. The long time required to obtain a cure, or even an arrest, of the disease by the climatic and open-air method, and the necessary expenses it entailed, when added to the loss of income incident to months of enforced idleness, seemed to put the practical application of this method of cure beyond the reach of the majority of individuals who have to earn their own living. An institution that would offer this opportunity and a return to a life of usefulness to working-men and women at a moderate cost seemed an urgent necessity, and induced me to attempt the establishment of such an institution and put the methods so long advocated by Brehmer to a practical test.

In view of the present widespread agitation on the subject of tuberculosis, I have thought at this time some of the experiences and results obtained during the past fifteen years while developing the first sanitarium in America for the treatment of pulmonary tuberculosis in persons of moderate means might prove of interest.

In looking back it seems curious to note, while every new consumption cure advocated has at once been eagerly taken up and tested, how slowly the rational teachings of Brehmer in regard to the treatment of the disease came to be generally accepted even abroad, while in this country the value of his methods is only now beginning to be realized.

I will not weary you with a detailed description of the Adirondack Cottage Sanitarium, its history, its struggle for existence, or its growth and development, but will merely touch briefly on a few points which relate to the class of patients it tries to cure or relieve, call your attention to a few features of the treatment, and lay before you the results obtained during the past fifteen years. My acknowledgments for valuable assistance and support are due to the late Dr. Alfred L. Loomis, to Dr. E. G. Janeway, Dr. Walter B. James, Dr. H. P. Loomis, and Dr. E. R. Baldwin, who for many years have examined without remuneration applicants for admission to the institution.

The two requisites for admission are that the patient should be unable to pay the usual prices charged in the region, and that he should be in the incipient stages of the disease. Five dollars a week has been the uniform charge to all alike; no graded rates or private patients; no charge for medical attendance; the deficiency in the running expenses being made up each year by subscriptions. It is a pleasure to me to state that during the past fifteen years not only has money enough to meet this deficiency been always forthcoming, but that the growth and development of the institution has been rendered possible by what has been put aside each year over and above the amount necessary to meet the running expenses, the plant paid for and entirely free from debt, and that enough has been saved to accumulate a Free Bed Fund of $18,000 and an Endowment Fund of $150,000.

Experience has shown most forcibly that the success of institutional treatment depends on the early detection of the disease. It has been found that 68 per cent. of the truly incipient cases were discharged as apparently cured, while only 11 per cent. of the advanced and none of the far-advanced cases recovered. We must recognize more and more the evident limitations of physical examination alone, and the dictum so often assumed that the disease is not present if nothing can be detected by this method seems to me utterly untenable. The pretuberculous stage of tuberculosis, so much written about, is nothing more than the first stage of tuberculous infection before physical signs have appeared. In the first stages of miliary tuberculosis of the lungs there are no appreciable physical signs, and no physical examination can be expected to detect the onset of tuberculous infection in the glands or deep tissues and organs of the body.

In attempting to make an early diagnosis in

obscure cases, of late I have occasionally been assisted in reaching a conclusion by a careful X-ray examination, and, where it was necessary, by the tuberculin test. I have had on several occasions a practical demonstration that an examination with a good X-ray machine and the fluoroscope may in early cases be of service in affording additional evidence of the presence of the disease. The diaphragm is seen to be higher on the suspected side or its excursion diminished on one or both sides, and in many cases a slight shadow can also be detected at the site of the suspected lesion. Of course, this may occur as the result of any other pathological condition which tends to diminish the expansive action of the lungs and impair their transparency, such as areas of pneumonic infiltration, bronchitis, etc., but if the history and rational signs are carefully considered these may generally be excluded.

If additional and more conclusive evidence is required, the tuberculin test should be applied. By a resort to this test a positive opinion one way or the other can often be reached, and if the initial dose does not exceed one milligram the constitutional disturbance caused by it is slight. No injury to the patient has in my experience ever resulted from such a test. During the past two years I have seen several cases in which a slight impairment of health, without cough, physical signs, or appreciable rise of temperature, being the only symptom present, a diagnosis of tuberculosis was made possible by a study of the fluoroscope picture, and, if this proved negative the application of the tuberculin test; the correctness of the diagnosis being confirmed later by the appearance of physical signs in the chest, of hemoptysis, or of cough, expectoration and bacilli. One case which I saw during the earlier part of last summer illustrates these points. Repeated physical examinations by experts of undoubted skill had been negative; the X-ray picture was inconclusive; there was no cough or expectoration, the only symptoms present being some loss of weight and strength, and a temperature which occasionally touched 99.5° F. in the evening. The patient was a physician and insisted on a diagnosis, therefore I advised the tuberculin test. Two milligrams gave a typical reaction. He obtained a year's leave of absence and went West. A few months later he wrote me he had gained twenty pounds, and that no one believed he had ever had tuberculosis. Recently I received a letter from him stating that one morning, after some unusual physical exertion the previous day, he had spit a teaspoonful of blood, and that on being examined by a physician he had been told that there was a slight pleuritic friction-sound behind the right scapula.

The scope of this paper will not allow me to discuss the details of institutional treatment, of which the main factors are an invigorating climate, an open-air life, rest, coupled with a careful regulation of the daily habits, an abundant supply of nutritious food, with the exhibition of such tonic and restorative measures as may be indicated in each case. I think, however, the favorable influence of rest on the course of a tuberculous process is not generally recognized. Surgery has taught us that activity of a part affected with tuberculosis always tends to aggravate the disease and to render it progressive. A tuberculous joint may often be cured by simple immobilization, while it will go on to destruction if the patient be allowed to use it at will. In advanced tuberculous ulceration of the larynx, where it becomes necessary to perform tracheotomy, the rest afforded to the parts by the operation is at once followed by a remarkable improvement in the disease in the larynx. Murphy's proposed treatment, which consists in putting the

FIG. 1.

The Main Hospital.

diseased lung completely at rest by introducing nitrogen gas into the pleural cavity, is another proof of the recognition by the surgeon of the value of absolute rest.

Absolute rest, as long as it is taken in the open air, is the best measure at our command to reduce the pyrexia of tuberculosis, to conserve the patient's energies, to abort the activity of the process, and to encourage the formation of fibrous tissue about it. The objection that a patient cannot digest if he does not exercise does not seem generally to be supported by experience, as most of the patients, while living out of doors and kept absolutely at rest, eat and digest an amount of food that would suffice for laboring men.

Specific methods of treatment have been very little used at the Sanitarium with the exception of tuberculin,[1] which has been employed with the utmost care for the past eight years, in selected cases, in order that some evidence as to its healing or immunizing influence, when given under the most favorable conditions of environment, might be obtained. Tuberculin treatment is apparently injurious rather than beneficial in all those forms in which the disease is actively progressing, or where there is any marked fever or constitutional impairment. It is evident that the addition of more toxin to an organism already unable to cope successfully with that produced by the disease would not be likely to be beneficial. Such treatment would find a parallel case in an attempt to produce immunity by injecting more diphtheria toxin in the case of a child with diphtheria already overwhelmed by the poisonous substances elaborated by the germs.

The exhibition of tuberculin has been confined at the Sanitarium to apyretic cases, or those that were nearly so, if well nourished and with moderate lesions, the diagnosis of the disease being confirmed in every case by a microscopical examination of the expectoration. The treatment should be begun with a minimum dose, very gradually increased, and with lengthening intervals, so as to avoid the production of constitutional symptoms, except, perhaps, occasionally a slight rise of temperature, and continuing the injections for several months, until no general reaction is produced even by large doses; the nutrition of the patient being closely watched and the injections continued only so long as the weight is kept up and the nutritive condition remains at a high standard. In other words, the aim being to produce repeated local reactions with but slight or no general reaction and gradual habituation to the tuberculin toxin. The doses and the interval between them should be carefully adapted to the needs of each case, and the best results by this method are obtained only with care, patience, and skill. Time is also an important element and my experience has seemed to confirm that of Petruschky in so far as the necessity of repeating a course of injections after an interval of several months, when susceptibility to reaction has returned. The reason for this is obvious when we reflect that all tuberculous foci in the body are not at the same stage of their development when the treatment is begun. When applied with care, avoiding the production of violent reaction and high fever, I have never seen any evidence that would lead me to think that the treatment had proved injurious at any time to the patients who were subjected to it.

Time will not allow me to discuss the various opinions held as to the nature of tuberculin reaction, or the question of artificial immunity in this disease, but I will merely lay before you, so far as it can be done by figures, the results of this treatment to the human subject under the most favorable conditions of environment, in so far as they relate to any apparent curative influence of the injections and to any immunizing effect as shown by the prevention of relapse. I have selected only the cases treated since 1894, as before that the details of the method were less understood, and it was often only temporarily applied. Since 1894 fifty-six cases have been treated by this method. It has been possible to follow the results in only fifty. Of these I have taken only the incipient cases, so as to avoid as much as possible errors of classification, although the results in the cases classed as advanced were proportionately somewhat more favorable.

There were 24 incipient cases and of these 20, or 83 per cent., were discharged as apparently cured. For comparison, if we take the last 113 incipient cases treated at the Sanitarium by climatic and open-air methods alone during the past three years, 82, or a little over 72 per cent were discharged as apparently cured; so it would appear from these figures that tuberculin had had some favorable influence on the results. Some little allowance, however, must be made for the fact that, even though all these cases were classed as incipient, those treated with tuberculin were selected with especial care. In order to procure some evidences as to the immunizing effect of this treatment and its power to prevent relapses, an attempt has been made to trace fifty apparently cured, tuberculin-treated cases and, for comparison, fifty untreated cases which corresponded as exactly as possible in point of classification on admission and discharge, and which were in the institution at the same time and remained the same length of time, have been studied with the results shown in the following tables:

[1] Koch's original tuberculin was used at the Sanitarium for a year after the announcement by this investigator of this new method of treatment. From that time, however, all the tuberculin has been produced at the Saranac Laboratory, and has been modified according to the indications which the latest researches on this subject seemed to call for. For several years a tuberculin made like Hunter's modification B. was principally in use. The general plan of separating the albumoses from the culture fluid laid down by Hunter was adopted, except that no heat was used at any time in the process. Before making an extensive trial of Koch's new TR tuberculin, it was thought best to study this substance in the laboratory. The researches made there by Dr. E. R. Baldwin and myself showed that samples of TR, as it was first put on the market, contained living tubercle bacilli, and for this reason the substance as then produced was considered unsuitable for the treatment of human tuberculosis. Dr. Baldwin has also recently shown that, although the directions accompanying the bottles of the new TR tuberculin state that it contains ten milligrammes of solid substance, if the water and glycerin be evaporated only about four milligrammes of solid substance remain.

During the past year Hahn's tuberculo-plasmine made after the method of Buchner and Hahn, of crushing the bacteria with excessive hydraulic pressure, has been used in a limited number of cases.

Sanitarium thus far has led me to believe that, when carefully applied in suitable cases, it has proved apparently free from any danger, and that it has seemed to have some favorable influence in bringing about healing of the lesions, probably by inciting the formation of fibrous tissue. In this it resembles Landerer's treatment by injections of cinnamate of soda, this substance producing a local and general leucocytosis and stimulating the formation of fibrous tissue around the tubercle and thus tending to limit the disease. That a certain reaction of the tissues, as evidenced by vascular hyperemia and leucocytosis, is capable of favorably influencing a tuberculous process, is shown in the cure of peritoneal tuberculosis by laparotomy, which occurs as the result of the hyperemia of the tissues brought about by the traumatism of the operation and their exposure to the air.

The immunizing effect of tuberculin as observed in the human subject would appear to be more uncertain both as to degree and duration, and artificial immunity is still the unattained goal of experimental research. While the evidence, therefore, as presented by the cases treated with tuberculin at the Sanitarium is somewhat favor-

FIG. 2.

The Inslee Cottage.

Of the 50 tuberculin-treated cases discharged apparently cured at varying periods since 1891, 3 could not be traced and 41 remain well to this date. If we take 50 untreated patients who were also discharged apparently cured at the same periods of time, and leave out three to correspond with untraced tuberculin-treated cases, 36 up to date are known to have remained well. These figures show a slight percentage in favor of the tuberculin cases, but, unfortunately, are not perhaps sufficiently marked to be in any way conclusive.

My experience with tuberculin treatment at the able to this form of treatment, it is restricted as yet to a very limited number of cases, and it must be admitted that these are usually such as are likely to recover under climatic and open-air methods alone.

The exact results obtained at the institution by the combined climatic and sanitarium treatment are difficult to express in figures, because they are generally influenced by the class of cases accepted. With advancing familiarity with the disease and improved methods of diagnosis, our standards have also steadily altered, so that what would have been considered an incipient case fif-

teen years ago would be classed as an advanced one to-day in most instances. Furthermore, the term "cure" can also be used only in a relative sense, time as measured by years being the only criterion of cure. Of late the results obtained have been better than formerly and this is due, no doubt, not only to improvements in methods and plant, but to the fact that more really favorable and early cases are available than formerly.

In making out the yearly reports of the institution, I have adopted from the first and printed in each report the following classification, imperfect as I feel it to be, as the best I could devise to express the classes of patients admitted and the results obtained:

Definition of Terms Employed.

1. *Incipient.*—Cases in which both the physical and rational signs point to but slight local and constitutional involvement.

2. *Advanced.*—Cases in which the localized disease-process is either extensive or in an advanced stage, or where, with a comparatively slight amount of pulmonary involvement, the rational signs point to grave constitutional impairment or to some complication.

3. *Far Advanced.*—Cases in which both the rational and physical signs warrant the term.

4. *Apparently Cured.*—Cases in which the rational signs of phthisis and the bacilli in the expectoration have been absent for at least three months or who have no expectoration at all; any abnormal physical signs remaining being interpreted as indicative of a healed lesion.

5. *Arrested.*—Cases in which cough, expectoration, and bacilli are still present, but in which all constitutional disturbance has disappeared for several months; the physical signs being interpreted as indicative of a retrogressive or arrested process.

An idea of the best results obtained thus far can perhaps be gained by a glance at the following table, copied from the last three annual reports, 1897-98-99, provided the figures are considered together with the classification adopted. Patients who have remained less than three months are put in a separate class, as little can be accomplished in the way of permanent results while in the institution for so short a period.

A glance at the table shows the following: Out of 323 patients who remained an average of 8¾ months in the institution, 113 of which were classed as incipient cases, 151 as advanced, and

FIG. 3.

"Taking the Cure" in Winter.

59 as far-advanced, 109 were discharged apparently cured, 104 with the disease arrested, 73 improved, 31 unimproved or failed, and 6 died. This gives the best results as yet attained at the sanitarium; *i.e.*, 33 per cent. of apparent cures, and 32 per cent. of cases in which the disease was arrested.

TABLE.

Patients who Remained an Average of 8¾ Months.

Condition of patients when admitted	Apparently cured	Disease Arrested	Improved	Unimproved or failed	Died
Incipient Cases, 113	82=72.566%	25	4	2	0
Advanced " 151	27=17.88%	67	43	13	1
Far " " 59	0	12	26	16	5
Total, 323	109=33.746%	104	73	31	6

If we study the gross results in the 1200 patients admitted during the past fifteen years, the result is as follows:

Twenty-three per cent. were discharged as apparently cured; 56 per cent. were discharged with the disease arrested or much improved; 19 per cent. were discharged stationary or unimproved; 2 per cent. died in the institution.

I am quite aware that cure in tuberculosis is but a relative term and that time is the only test of cure; a test which becomes more and more discouraging as the period of its application lengthens and we become more familiar with the relapsing nature of the disease. Nevertheless we have attempted to determine as far as was practicable the permanency of the results obtained, extending over a period of fifteen years to date. Of the 1176 patients discharged alive about one-half are still living, and one-half of this number have been heard from as being perfectly well. This proportion of one-quarter of the whole number covers the entire fifteen years, and the percentage, of course, improves each year as more early cases are admitted. The permanency of the recoveries depends necessarily a good deal on the environment to which the patient returns. If he is obliged to go back to a laborious life or an indoor occupation he is much more likely to relapse than if it is possible for him to return to a good climate and an outdoor existence.

The education which the patients receive at the sanitarium as to the nature of their disease and the methods to be relied upon in combating it is of the utmost value to them, enabling them to preserve their health and avoid relapses after they have left the institution; and this education is not limited to themselves, but is imparted by them to the great mass of people with whom they come in contact.

In addition, the attempt to cure pulmonary tuberculosis by institutional treatment and the practical demonstration which it has given of the possibility of accomplishing this in many cases have cast a ray of light on one of the darkest problems which confront medical science and have proved an object-lesson which has, perhaps, not been without influence in creating the present popular demand that the State supplement private philanthropy in the establishment of similar institutions under its control.

THE PREVENTION OF SCARLET FEVER.[1]

BY FLOYD M. CRANDALL, M.D.,
OF NEW YORK:
ADJUNCT PROFESSOR OF PEDIATRICS IN THE NEW YORK POLYCLINIC; CONSULTING PHYSICIAN TO THE CHILDREN'S AND INFANTS' HOSPITALS.

In few other diseases are preventive measures so productive of good results as in scarlet fever. Although a far more serious disease than measles and most of the other infectious diseases, its spread may be more effectively controlled. No one will allege that the measures necessary to the attainment of that end can be carried out without encountering difficulties. They are many in number and very complex and demand on the part of the practitioner much thought and perseverance. But they are effective in preventing the spread of the disease, and the conscientious physician will not regard the difficulties encountered as an adequate excuse for their non-enforcement. When we consider the high mortality of scarlet fever and the grave sequelæ which are common in those who survive, we are forced to feel that neglect of preventive measures is little short of criminal. Nevertheless important details of prophylaxis are not infrequently ignored or completely forgotten by the attending physician. Certain measures are sometimes rigidly enforced while others of equal importance are neglected. The disease may thus be spread broadcast by leaving a single loop-hole unguarded. It is the design of this paper, therefore, to call attention to certain details in management and prevention upon which error is frequently made. Time forbids an exhaustive discussion of the whole subject of prophylaxis of scarlet fever and no such effort will be made .

The isolation of children known to have been exposed to scarlet fever may not be strictly necessary, but close observation is an important measure of prevention. It is true that the disease is not contagious during the period of incubation. It is doubtful, indeed, whether it is contagious before the appearance of the eruption. Evidence has recently been presented to show that children in contact with scarlet-fever patients for several hours after the initial vomiting have not contracted the disease. Still, it is difficult to rid oneself of the fear that there may be exceptions to the rule and that exposure during an early stage may in some cases be followed by serious results. The fact, however, that as a rule contagion is not active until the eruption has developed is an extremely important one and renders isolation during the latter stages far more effective and, hence, of greater importance. We

[1] Read before the New York Academy of Medicine, April 5, 1900.

have thus in scarlet fever a distinct advantage over measles, for in the latter disease the period of contagion begins two or three days before the appearance of the eruption.

As the period of incubation in scarlet fever is short and somewhat variable, every child who is known to have been exposed should be isolated. Following the general law that the more severe the disease, the shorter the incubation, the period of incubation in scarlet fever is rarely more than four days. In my own experience, a period of about two days has been the most common and I have seen a case in which it was but little over twelve hours. In nearly 90 per cent. of the cases it is between two and six days. Although a feeling of security is warranted after four days, no person, who has been exposed, should be considered safe for less than a week.

The question of sending the other children away from home is often a serious one. The objection is frequently made that they may carry the disease to other places, or the parents are unwilling to have them ill away from home. These are valid objections if the fears are well founded. The decision must rest largely on the time of the exposure. If the exposure occurred before the appearance of the eruption, there may be little fear that the disease has been contracted. If exposure occurred during the stage of eruption, the probability of illness will be great. If the patient is isolated soon after the initial symtoms have appeared, other children in the family are very unlikely to have taken the disease from him.

Whatever may be thought of the propriety of isolation during the period of incubation, there can be no doubt of its importance after the first symptoms have appeared, for the rash, together with the possibility of infection, appears often within twelve hours after the invasion. Four symptoms, when occurring in combination, are extremely suspicious of scarlet fever, *i. e.*, vomiting, fever, rapid pulse, and sore throat. The vomiting, as a rule, occurs suddenly with little or no nausea. It is forcible and sometimes projectile in character. It may occur but once or may be repeated several times during the first twelve hours. In my own experience, it has been a constant symptom.

The temperature rises rapidly and naturally ranges high in scarlet fever. In mild cases it may be found at the first visit not above 101° F., but it is frequently 103° or 104° F. I once examined a child whose sister had become ill with scarlet fever the day before. The temperature was normal and apparently she was in usual health. I had scarcely left the house before she was seized with vomiting and I was at once recalled. On my return, in little more than an hour, the temperature was 102.5° F. and the throat was decidedly red.

I have come to regard an abnormally rapid pulse as a symptom of considerable importance. I would by no means call it pathognomonic and possibly not diagnostic; but it is certainly very suggestive. A pulse of 150 at the outset is not unusual.

Sore throat is usually complained of early. At the first visit, as a rule, the hard palate and pillars of the fauces will usually be found red and congested. Sometimes the peculiar exanthem of scarlet fever will be seen thus early. This consists of numerous minute dark red macules on a reddened base, scattered over the hard palate. Frequently, however, at the outset nothing but diffuse redness will appear. Patches of pseudomembrane may occasionally be seen at the first examination but they are not common before the third day. The tonsils may be smeared over with a tenacious exudate closely resembling pseudomembrane. There is not infrequently a nasal discharge, which may consist of clear tenacious mucus or muco-pus. In mild cases the throat symptoms at the outset may be slight.

I would not be understood as considering the symptom complex of vomiting, fever, rapid pulse, and sore throat as affording positive evidence of scarlet fever. They are sometimes seen in other conditions in young children, notably acute indigestion and *la grippe*. They are, however, always suggestive of scarlet fever, sufficiently so, in fact, to warrant the isolation of the patient until their significance has been more fully demonstrated. The appearance of an eruption following within twenty-four hours after such an onset in the vast majority of cases is sufficient to establish a diagnosis. The practitioner will frequently see, however, cases of a mild type whose early diagnosis is extremely difficult. Even in mild cases there is usually an onset of vomiting with slight fever and sore throat. During the past few months, most practitioners in New York have undoubtedly seen cases of *la grippe* accompanied by an eruption which simulated that of scarlet fever. The fever, sore throat, flushed face, and perhaps nausea, followed after a short time by a rash, have made up a picture very suspicious of scarlet fever. While it is possible that cases of real scarlet fever have been considered as influenza, it is certain that there has been a considerable number of cases of *la grippe* with an eruption.

The strawberry tongue is not an early symptom of scarlet fever. The strawberry tongue is an especial favorite with young doctors. They see it frequently and are always alarmed by it. A white tongue with red spots is not characteristic of scarlet fever in the slightest degree but is seen in every-day practice. The term should be restricted to the red tongue with enlarged papillæ which follows a coated tongue on the third or fourth day of the disease. Flint was among the first, if not the first, to describe this peculiar appearance of the tongue, which he did in the following words: "The tongue early in the disease is generally coated. While the coating remains, frequently the papillæ projecting through it have the appearance of numerous red points; the surface of the tongue looks as if cayenne

pepper or red sand had been sprinkled over it. This is seen in other affections. Another appearance is quite distinctive of scarlet fever. In the progress of the disease, the coating exfoliates, leaving the surface of the tongue clean and reddened; and the papillæ being enlarged, the appearance is strikingly like that of a red strawberry. The strawberry-like tongue is a pathognomonic symptom; it is peculiar to this disease. It is often but not uniformly present."

The strawberry is not a white fruit with red seeds, but a dark red fruit with a rough surface. It is taxing the imagination, therefore, to apply the name of strawberry to a white tongue, and totally untenable to lay stress on such a tongue in the early diagnosis of scarlet fever. I am well aware that several prominent writers have done this, but I scarcely need to remind you that an error once started on the rounds of medical literature is very hard to kill. It will sometimes creep into the work of the most careful of writers.

The patient having passed through the acute stages of the disease, the question arises as to how long he is capable of infecting others, and, as a corollary, how long he should be isolated. It is commonly stated that the most infectious period is during the height of the eruption. This is undoubtedly true. There is then a decline in the infectious power, which is again followed by a period in which that power is renewed. The latter occurs during the stage of desquamation. The patient is dangerous to others as long as the slightest desquamation continues on any portion of the skin. The duration of this period is extremely variable, and the most common error, perhaps, consists in being guided by a fixed number of days. The conventional forty days is only to be regarded as approximate. It is rarely too long. Desquamation is liable to persist in small areas of the body after it has disappeared from other portions. It is frequently very difficult to determine in such cases whether we have to deal with a local patch of scarlatinal desquamation or with eczema brought about, perhaps, by irritation, the result, it may be, of overzealousness in bathing and anointing. These circumscribed areas are most commonly found about the flexures of the joints.

Desquamation is liable to persist about the finger-nails after it has disappeared from every other part of the body. There can be no more dangerous place for such persistence, for the scales are liable to fall on any article which the patient may touch and may hence be conveyed to a distance. There are innumerable authentic cases of conveyance of the disease through letters written by desquamating hands. I have myself known of such an occurrence, the letter coming several hundred miles through the mails. The hands and fingers should be particularly scrutinized before the quarantine is raised.

The question of secondary and tertiary desquamation is interesting from the standpoint of prophylaxis. The scales from these desquamations are certainly less infectious than those of the primary desquamation. It is the belief of some observers that they are not capable of conveying the disease. There seems to be authentic evidence, however, that even in tertiary desquamation the scales have been infective and it is the part of wisdom, therefore, to regard every such case as unsafe. Until a specific germ is discovered, these questions must be determined solely by clinical observation and there will be, as a necessary result, a greater or less degree of uncertainty.

Desquamation is not the only factor by which the period of isolation is to be determined. Purulent discharges certainly contain the infective principle of scarlet fever. After it, no child who is still suffering from otitis, chronic pharyngitis, purulen coryza, suppurating glands, or a purulent discharge of any kind, should be allowed to mingle with others. Holt refers to a case in which the opening of a post-scarlatinal empyema in a surgical ward was followed by an outbreak of scarlet fever, and to another case in which the disease was communicated through a purulent nasal discharge after eleven weeks. Ashby insists upon retaining all cases in the hospital for forty-two days and discharging none until desquamation is complete. Still, he has found that from 2 to 4 per cent. of such cases are infective.

These dangers have not been sufficiently recognized and as a result the disease has undoubtedly been communicated to thousands of children. A consideration of facts, as demonstrated by authenticated cases, proves the unwisdom of adopting any single period as necessary for the quarantine of scarlet fever. In many cases six weeks is ample and the patient may be released with perfect safety to others. In other cases he is almost as dangerous at this period as in the first week of the eruption. The rule should be, not a fixed number of days or weeks, but the time that is necessary for the disappearance of all desquamation and of every kind of purulent discharge.

The question of infection after release from quarantine has of late been the subject of some discussion in England, and an attempt has been made to prevent more fully what they there call "return cases." At the Monsall Fever Hospital of Manchester, for example, the following method has been adopted: Certain wooden pavilions are set apart as convalescent wards for scarlet-fever cases, no case being sent into these wards until six weeks have elapsed from the onset of the illness. Even then desquamation, as well as all purulent discharges, must have ceased. The convalescent children are encouraged to take exercise freely in the open air. I am unable to say how long they are retained in these wards, but the statement is made that since this system has been in operation there has been no "return case," although they were not uncommon before that time.

The question regarding the isolation of mild

but undoubted cases of scarlet fever is frequently a trying one. In some of these, desquamation is very slight and there is no purulent discharge. It is undoubtedly a fact that the quarantine can be raised in a few of these cases in less than six weeks. Still the desquamation, even when slight, is liable to continue for a greater period than its intensity might lead one to expect, and these mild cases require more than ordinary precaution.

Grave errors are constantly being committed by physicians in making a diagnosis of German measles, roseola, or stomach rash, when the condition is in fact mild scarlet fever. Such diagnoses are sometimes more than errors; they are grave sins. It is through these mild cases that the disease is spread broadcast. Not only are such cases dangerous to the members of their own families but to others who come in contact with them in the most unsuspecting manner. Every doubtful case should be isolated until the appearance or non-appearance of desquamation aids in determining its true character. Reasonable parents do not object to such caution. There are few who do not prefer the trouble involved by temporary isolation to the danger of exposing other children. Unfortunately, parents are not always reasonable, and it is but justice to physicians to say that they are not in every case as gravely at fault as it might seem.

The question of school attendance immediately arises upon releasing a child from quarantine. The Health Board of this city wisely requires a certificate from one of its own inspectors before a child who has been excluded from school can be re-admitted. The system of school inspection now in force in New York cannot be too highly commended. Its value and importance are amply shown by the fact that last year there were excluded from the city schools 32 cases of scarlet fever, 133 cases of diphtheria, 253 cases of measles, 276 case of pertussis and 1627 cases of contagious eye-disease.

At present the means by which the New York schools are chiefly instrumental in disseminating scarlet fever is through the clothing of children who may have come from families in which the disease exists. It is true that children from such families are supposed to be excluded from school, but there are unquestionably many unreported and concealed cases, which thus become dangerous to others through mediate infection.

The question of the advisability of closing schools in the case of an epidemic of scarlet fever must be settled differently in different communities. In the country and in small towns, where the children will be separated from each other when the schools are closed, their closure may be an important measure of prevention. Moreover, in such communities the various families are known to each other. Illness is at once known and contagion guarded against. In large cities, on the other hand, the conditions are quite different, particularly in the crowded tenement regions. Here the children cannot and will not be confined to their homes, but will mingle with each other all day long. Closing of the schools will not prevent it. In addition to this, the daily inspection of the children in school is a great safeguard against the spread of disease. Under present conditions in New York, the closing of the schools for the purpose of preventing such diseases as scarlet fever and diphtheria would unquestionably produce a result quite the contrary.

The importance of hospitals for the treatment of scarlet fever and diphtheria is not yet fully appreciated by the profession. We have now in New York hospitals designed to meet every requirement in this direction. At the Willard Parker Hospital no case is refused because of inability to pay. It has unquestionably been the means of saving the lives of many children, not only of those suffering from the disease, but of others who would have been exposed had the patient been left in his home. More recently, the Minturn Hospital has been established to relieve a very urgent need. There are many people in a great city, able and willing to pay for treatment, who are so situated that isolation of infectious diseases cannot be enforced, or can be enforced only at great expense and trouble. Well-to-do people living in hotels, boarding houses, or apartments, or visiting relatives, have sometimes been placed in dire straits by the development in a child of scarlet fever or diphtheria. To such this hospital is a most beneficial institution. There, every advantage may be obtained, which can be afforded by cheerful and sanitary surroundings, trained nursing, and skilled medical attendance. The outlay is light when one considers the expense which necessarily accompanies a serious infectious disease. Should the parents desire, their own physician can attend the patient. A parent or friend may remain constantly with the child, being subjected only to the same rules regarding isolation and quarantine that are applied to all inmates of the hospital.

It cannot be denied that medical men through carelessness have sometimes been instrumental in carrying scarlet fever. No other disease is so frequently transmitted through the agency of clothing. Sputa, coughed out during examination, or scales adhering to the clothes may cause the disease in other children upon whom the doctor may be in attendance. I feel justified in making the statement that the practitioner should never visit a case of scarlet fever without wearing a gown. Such a gown can be made very cheaply of cotton cloth. It should be made to button closely about the neck and wrists and should be long enough to reach to the feet. When beginning the treatment of a patient with either of these diseases, one of these gowns should be taken to the house. It should be put on before entering the sick-room and should be hung up in the bathroom or other suitable place upon leaving. A cap to protect the hair is desirable, but not so necessary as the gown. Upon the termination of the case the gown can be thoroughly

boiled and used again. The trouble and expense involved are thus trifling. In a considerable experience, I have never found a child or parent who objected to it. On the contrary, it inspires confidence in the physician as a careful man, and removes the possibility of his ever being charged with bringing the disease into the house, should its occurrence in one of his families be unexplainable. It is a safeguard both for the physician and his patients.

It goes without saying that the hands and face should be disinfected after every visit to a scarlet-fever patient. The same is true of the stethoscope, which should be used for all physical examinations of the chest. The tongue-depressor or any other instrument used about the throat should not be taken from the room. The doctor himself should not carry out the details of treatment farther than is strictly necessary. It is difficult for him to do so without danger of carrying the disease. It can only be avoided by more thorough disinfection than most doctors are willing to carry out. In few diseases is the importance of a qualified nurse greater than in scarlet fever. One should be secured wherever it is possible. Not only are the details of prevention and treatment carried out more thoroughly and satisfactorily, but the doctor is relieved of many duties which he should not be obliged personally to perform. The value of a competent nurse in scarlet fever can hardly be overstated.

The selection of the sick-room is of much importance. In tenement-houses and flats there is but little room for choice. The child should be placed in the front room and should never be allowed to remain in a middle room or dark room. The door in the hall should be sealed with strips of paper, as is done in fumigating. The door communicating with the rest of the apartment should be kept closed, and the children should be kept in the rear rooms, even if it is necessary to remove the beds from the intervening rooms. If possible, the other children should be sent away. If the parents are intelligent and faithful in obeying instructions, the spread of the disease may be prevented, even in a small flat, but it is very difficult and will require unremitting vigilance during its whole prolonged course. It is practically impossible if there is but one person to care for the sick and look after the well. To ensure any safety whatever, the nurse must be isolated, as well as the patient.

Whether the patient lives in a flat or in a house, the ease of preventing the spread of the disease is greatly augmented if there can be a third person to act as intermediary between the nurse and the person who has the care of the other children. To this person may be assigned the duty of carrying the food and various articles required by the nurse and of carrying away the soiled clothing and performing the numerous offices outside the sick-room. She thus needs to come in direct contact with neither the sick nor the well. In the houses of the well-to-do, where nurses are employed, a trusted servant may fulfil this office. It is a hardship for the mother to make a choice between the invalid and the other children, particularly if they be small, but the necessity of her doing so if of the greatest importance. The statement frequently made that the nurse should not eat or sleep in the room with the patient is entirely proper, if such an arrangement can be carried out. It is usually impossible, however, in any except well-to-do families, where a whole floor can be utilized. Where such an arrangement can be made, the conditions are the most satisfactory than can be devised. When a floor is not available, the room should be selected which can be most readily isolated and will at the same time be convenient and habitable for the attendants. Six weeks' confinement to a single room is a trying ordeal, and isolation during the last days of the period can be more strictly enforced if the room is cheerful and comfortable. While a room at the top of the house is for many reasons the most desirable, one on the floor below should be selected should there be no bathroom on the top floor. The passing to-and-fro to the bathroom will frequently undo all other efforts at isolation, not to speak of the additional labor involved. A most satisfactory arrangement is a back room on an upper floor opening into a bathroom, the latter having also a second door into the hall. Two doors thus intervene between the hall and sick-room. By placing a small gas-stove in the bathroom much labor is saved and isolation can be made complete. I have recently attended a case in a family of young children in which the sick-room was thus arranged and was but one flight up. All cracks and key-holes were covered with strips of paper, the room being thus hermetically sealed against the rest of the house, except for the passage through the bathroom. The disease in this family was limited to one child.

The hanging of dampened sheets before the doors is a measure of some practical value. It is not to be supposed that they can disinfect the air or destroy the germs, but they do prevent currents of air when the doors are opened and are a constant reminder of the necessity of care.

The preparing of one room for a sick-room in a house where there are children is a wise measure. Such a room is not infrequently found in modern houses and should be more common. It may be made as cheerful and as available for ordinary use as any other room. The walls and ceilings are painted or covered with washable paper. The floor is polished and covered with rugs instead of a carpet. The hangings are easily removable and there is no upholstered furniture. The furniture is of polished wood or white enamel and is made without carving or deep grooves. A room, thus arranged, can be quickly put into commission as a sick-room, and will greatly simplify the question of prophylaxis.

General inunction of the body is a most effective measure, both of treatment and prophylaxis. It may be begun as soon as the eruption

has appeared and should be continued until desquamation has ceased. This method, however, will vary in different stages. During the stage of eruption before desquamation has begun, a simple bland oil is most desirable. Antiseptics can be of little avail and all irritating preparations should be avoided. Lanoline is one of the best of these or a mixture of equal parts of lanoline and cold cream. These preparations, however, are somewhat expensive. Vaseline, therefore, may be employed in their stead, and is no doubt the most common preparation used. Some of the cheaper grades of yellow vaseline are decidedly irritating to some skins. When itching and irritation of the skin is great, a five-per-cent. ointment of boric acid and vaseline is sometimes effective. Sponging with a solution of borax and water, followed by carbolized vaseline, will also give temporary relief. Carbolized vaseline, however, should not be used over large surfaces. It is true that absorption is not active through the healthy skin; but in scarlet fever we do not have a healthy skin, and it seems quite possible that absorption might occur. In a disease in which the kidneys are frequently involved, it is unwise to run any risk of introducing so irritating a substance as carbolic acid.

After desquamation has begun, the objects of inunction are quite different. The procedure then becomes a matter of prevention as well as treatment and the most important object is to soften and remove the scales, thus preventing their dissemination with the resulting danger of spreading the infection. It is the belief of many that the scales may be disinfected by adding antiseptics to the oily substance used for inunction. This seems somewhat doubtful. It is a point, however, very difficult of decision by clinical observation and must be settled at some future time by the bacteriologist. The general fact is at least positively settled that proper care of the skin during the stage of desquamation is one of the most effective means of limiting the spread of the disease. Antiseptics may be added to the ointment or oil used for inunction. The boric-acid ointment already referred to is one of the best. A two-per-cent. ichthyol ointment has its advantages but is objectionable to many patients because of the odor. Carbolic ointment may be used over limited areas. During this stage the inunction may be preceded by a bath or sponging with water at the temperature of 90° F. The water may be plain or it may contain a small amount of salt or borax. The use of an antiseptic soap is advocated by many practitioners, resorcin soap being, perhaps, the most commonly used.

Ointments or oils of disagreeable odor are objectionable. The appetite is frequently poor and the problem of nourishment is difficult. It is easy to increase this anorexia by disagreeable odors. A preparation having even a slight odor becomes perceptible when applied to the whole surface of the body. Such odors are often intensified when applied to surfaces not open to the air, particularly when fever or perspiration is present. This is the chief objection to be urged against the animal fats, like lamb fat, mutton tallow, or beef suet. The bacon rind, popular in some parts of the country, has the same objection and possesses no advantages. Lard has but little odor, but it is difficult to obtain it pure in the cities. It is unstable and quickly becomes rancid. Fats are prone to become rancid by being broken up into glycerine and fatty acids. The physician should always make sure as to the character of the preparation used for inunction. A rancid fat in a severe case of scarlet fever may cause great irritation and prolong the period of desquamation.

There are many other matters of importance in the prevention and management of scarlet fever. As stated at the beginning of the paper, however, it was not my intention to consider them all, but certain ones only, which are most frequently neglected by the general practitioner. Opinions will no doubt differ as to the relative importance of these details and some may feel that measures have been omitted which are as important as some of those which have been included.

It must be remembered that in scarlet fever we have not the sure basis of knowledge which we possess in diphtheria. Until a specific germ has been discovered and its life-history studied, we must rely on clinical evidence alone. We must, therefore, expect to find differences of opinion on almost every detail of pathogenesis, prophylaxis, and treatment.

THE STATE OF NEW YORK AND THE PATHOLOGY OF INSANITY.

BY P. M. WISE, M.D.,
OF NEW YORK;
PRESIDENT OF THE NEW YORK STATE COMMISSION IN LUNACY; PRESIDENT OF THE AMERICAN MEDICO-PSYCHOLOGICAL ASSOCIATION.

THE leading chapter in the century's history of the care and treatment of the insane in America will be the humane and progressive record of the Empire State. From the ward for lunatics in the New York Hospital in Colonial days to the recent "State-Care Act," New York has been abreast if not foremost in this eleemosynary duty to its dependents, as the sentiment of the time has indicated. The tardiness in providing for all the dependent insane by the State was more than compensated by the imperial measures which carried the State care policy into effect. The great movement was not a revival of sentiment, supported by the emotions, creating a name, and then dying from inanition. It came to stay and it has been sustained faithfully, becoming a fixed public burden, and in this closing year of the century having no real opponent in the Government of the commonwealth. "State care" has not been a name without other merit. Its purpose has

[1] Read before the American Medico-Psychological Association May 22, 1900.

been realized in a remarkable degree. Remarkable in the fact that it is the only instance in the history of the States where the name has been merely an unrealized claim. There is to-day in the State of New York no acknowledged dependent insane person in an almshouse, penitentiary, jail, reformatory, or any place of custody other than a State hospital. Can this claim be made elsewhere? If so it is a glorious example of a fearless State Government following the precedent established by the Empire State. It is the antithesis of the shameful, cowardly, miserly policy of a wealthy State establishing almshouse-treatment of the insane by law; an example which should make its citizens responsible for it hide their faces from the Sun of Righteousness, who taught the doctrine of mercy and charity. "Inasmuch as ye have done it unto one of the least of these, my brethren, ye have done it unto me."

In carrying into practical effect the provisions of the State-Care Act, the supervisory body—the State Commission in Lunacy[1]—found it expedient to establish a basis of cooperation between all the hospitals and institutions in its Department. It was not only expedient but it was essentially requisite for the attainment of the great end in view—the most effective treatment and care of the insane in the most economical way. In addition to cooperation there must be a certain degree of uniformity in method and administrative practice. Not, take notice, in medical practice, for in this there was accorded the same freedom from interference and allowances which existed theretofore, or which now obtains elsewhere. If uniformity of therapeutics, personal treatment, classification or research, resulted in some degree, it came from association and not from direction. I can fearlessly appeal to the representatives of the Department, Superintendents of the State Hospitals, brother-members of this Association, who I am proud to refer to as the best representatives of psychiatric practice in New York, for a confirmation of this statement. It was the policy and practice of my predecessor, as it has been of the writer, to allow the widest scope within the limits of safety and the welfare of the patient, to individual effort and experimentation. Otherwise, progressive medicine would be a name only and dry rot an actuality. Thus, cooperation and a scientific franchise to hospital physicians has created a psychiatric practice in our State Hospitals which is unsurpassed, and which, I believe, will stand the test promulgated by a versatile neurologist, whose peerless imagination has been the delight of thousands in many editions and seven translations. However, it is well known that the prophetic and delightful parable painted in entrancing words by this masterful brother, was an actuality contemporaneous with his prophecy.

In investigation of the causes of insanity, in establishing the morbid anatomy of the brain, in pathological departments of hospitals for the insane, and in creating a special literature, New York has been a pioneer. The *American Journal of Insanity*, now in its fifty-sixth year, is the product of the Utica State Hospital in its earliest history. In his annual report for the year 1868, Dr. John P. Gray says: "I have long been convinced that the extensive field afforded by this institution for pathological investigation should be cultivated more thoroughly than could possibly be done by the ordinary medical staff." He called to the attention of the managers the importance of employing a profesional man of special attainments and skill in the department of pathology, to make microscopic examination of the nervous tissue, and to test the value of instruments of precision for diagnosis, "and such other pathological researches as might be deemed valuable to medical science and the public generally." In his report four years later, he gives a résumé of the work accomplished which appeared of sufficient importance to suggest legislative authority. A bill was unanimously passed the same year creating the position of special pathologist and providing for the equipment of the laboratory, which was accomplished with the aid of Dr. J. J. Woodward, then assistant surgeon, U. S. A. The following year Dr. Gray reports, "the results so far attained in this field of special investigation have fully justified the expectations we had formed of the value and importance to medical science and the public interests in recommending some years ago the organization of this department of research." There must be a number of those present who recall the fine technical work exhibited by Dr. Gray at several meetings of the Association about twenty-five years ago, as the product of the Utica laboratory. The experience at Utica and especially the causes which led to the decadence of the laboratory and finally to its extinction are worthy of consideration at this time, as they apply now, as they ever will, a lesson showing the mutual dependence of one department of medicine upon others in the scientific work of hospitals. The special pathologist at Utica for the first three years was a gifted physician, Dr. E. R. Hun. It was his work which created the law establishing the laboratory as a permanent institution. He was succeeded by Theodore Deecke, a philosopher but not a physician, a master of technic but ignorant of symptoms, a man jealous of his department, possessing scientific attainments of high order, but too little sympathy with the expression of insanity as witnessed constantly by the physicians of the staff. His work was admirable, but inanimate. He could show the morbid conditions, but could not relate them with the clinical facts, and as a consequence his work became a mechanical process and died from the same causes which will ever destroy values by the separation of clinical and pathological research. It is a lesson which should have been heeded. The work at Utica, however, was sufficiently impressive to mold into the organic laws of the four later State Hospitals, provision for a special pathologist. The privilege was accepted in only two of the hospitals and only for a short period.

[1] Hereafter referred to as the "Commission."

The lesson taught at Utica was undoubtedly a restraining cause, and it was rather to the strict and almost to the prohibitive separation of the pathological and clinical departments that the other hospitals united all medical work in the regular medical staff. Some admirable researches were conducted by members of the staff, which in practical value exceeded all that was accomplished at Utica during the existence of the special department. Small laboratories of great comparative merit were earnestly worked by some of the hospital physicians from time to time. Had the minor and technical difficulties been overcome by capable instruction in these instances, the results might have been what we hope for but have not seen. The difficulties that are encountered by the hospital physician who wants to unite his clinical work with pathological research are almost insurmountable. Technic, in the interval between college and the evolution of a fixed point in view, leaves him stranded and he must begin at the bottom for his preparation. By the time he is prepared for good work there may come promotion and burial in administrative duties. The work he has done may be too immature for application, has failed of record, and is lost to his successor. Here and there may be some brilliant discovery in its incipient stage, but without persistent research it is soon buried in a mass of detail and lost to view.

With the cooperative spirit which was the hematin of the life-blood of the State-Care Act, there was created the desire to unite pathological research, then in a more or less active stage in a number of the State Hospitals, in a scientific center. The initial proposition led to quite active argument and no little opposition grounded on common sense and experience. Perhaps the most forceful argument against this movement—and experience has actually proved it prophetic—was the belief and the claim of several superintendents that centralization of research in a great central laboratory would dampen the ardor of individual hospitals, and especially of individual members of the medical staff, who would be debarred from working on original lines without the approval of the central laboratory or the supervising pathologist.[1]

It is regretted that the discussion on the merits and demerits of centralizing research, which preceded the creation of the Pathological Institute, failed of record except in a few instances. The remaining impression of its astuteness, its prophetic foresight and the results which might reasonably be anticipated, would make it eminently fitted to supplement this discussion. At that time and for several years, the hospitals had accomplished much practical laboratory work chiefly related with clinical problems, although but little of the finer technical work had been attempted. Whatever was accomplished was wholly due to the praiseworthy spirit of research of individuals who would sacrifice selfish and personal interests and comforts to attain the end in view; and it may be recognized as a rule with no exceptions that from such material has developed the scientist of the class who has made pathology what it is today. The history of pathological advancement shows that it has not been the machinery and organization created with methodical acumen from an unlimited treasury to which is due original discoveries, but to the solitary individual, whose very needs create a stimulant, who, perhaps, in his earliest efforts before the possible demonstration, would have been mocked by a scientific center into discouragement and silence. The inception of revolutionary discoveries seems possible only to the isolated worker who ignores and defies skepticism, and who is independent of cooperative assistance. A Koch, a Pasteur, and a Lister would never have been known if their primal theories had required for elucidation the approval of some directing scientist clothed with autocratic powers. Hence, it was maintained—and correctly, I believe—that centralized research would retard if not give the death-blow to original individual efforts, unless they accorded with the "menu" of research in the central office. It is not held, I desire to emphasize, that such untoward conditions necessarily ensue upon centralization, but human tendencies are universally alike and the laws of action require an exception if results other than those described are realized. My observation, at least, of the short experience with centralized research in New York sustains the claim that the State Hospital Laboratory will cease to be a coadjutor of the central laboratory, as first designed, unless cooperation is made a requirement by the Commission.

In the fifth annual report of the Commission, for 1893, the subject of a pathologist is referred to in the following words: "The Commission would recur to the importance and desirability of

[1] From the Eighth Annual Report for the year 1894 of the St. Lawrence State Hospital. "Closely associated with the clinical study of insanity is that of pathological and etiological research. It is maintained that these questions, mighty in themselves, could better be assigned to some separate department of the State service; and this is undoubtedly true if the State desires to add to its eleemosynary work that of scientific investigation. It may well be considered doubtful if the State Government will look favorably upon this additional burden. It is also questionable if the results that would be obtained would far exceed previous efforts in pathological work carried on in a distinct department at one of the State Hospitals at large expense to the State. The usefulness of a central (or common) laboratory for all the State Hospitals will depend wholly upon the personnel of its organization, and the same chances will thus have to be taken that each medical superintendent assumes in the appointment of his medical staff officers, with less chance of correcting errors. The temptation to make a central laboratory useful for the community in which it is situated, and for the individual in its organization, to the exclusion of distant institutions, will not always be resisted. It will also reduce, if not dispossess, the individual hospitals of laboratory work, which is one of the strong inducements to young medical men to engage in hospital practice for temporary periods.

"It is well to consider also that the best results in science have not emanated from public and paid work, but from voluntary efforts and frequently from obscure sources. The brains of men cannot be prodded to produce, like the soil, but must be stimulated by an interest that needs more than a departmental service to maintain. The technical work of a central laboratory may produce some beautiful results, as a fruit of exquisite technic, but conclusions based thereon will be thoroughly worthless, except in a combined study of the clinical aspect of the case. The physician who studies the cause and indications of disease from frequent observation of the patient is the only competent person to reach conclusions from the morbid anatomy that will be of any value to the human race. . . . . In the functions of chemistry, bacteriology, and microscopy, annlied to clinical examination a central laboratory can give no aid except as an instructor. It is doubtful whether a central laboratory will be useful, except as a coadjutor to the hospital laboratory; and it is far better to maintain the latter in a state of efficiency, increase the medical force sufficiently to permit a greater measure of pathological work, and keep the several departments of disease research together.

"Peter M. Wise, M.D., Medical Superintendent."

appointing an experienced and competent pathologist who should act for all the hospitals of the State. . . . The Commission now has under advisement a proposition for the appointment of such a pathologist as soon as his selection and the arrangements for a suitable laboratory can be determined upon."

The discussion by the State Hospital Superintendents of the action contemplated by the Commission resulted, finally, in a united sentiment which was expressed in a resolution assenting to and approving of "the appointment of a pathologist of recognized reputation and qualifications, to be located in the city of New York, and preferably to be a teacher of pathology, the expenses to be borne by equal monthly payments from the funds of the several State Hospitals."

In the sixth annual report of the Commission, for 1894, it recommended "that provision be made for the establishment and maintenance of a pathological laboratory or institute, under the direction of an accredited and competent pathologist, which shall be a department of the State Hospital system, to be maintained primarily for the State Hospitals, but incidentally for the benefit of all the institutions for the insane, as well as for such members of the medical profession at large, especially alienists and neurologists, as may desire under proper restrictions to avail themselves of its facilities in their investigations of the anatomy, physiology and pathology of the brain and nervous system." It will be observed that the Commission had in view primarily the benefit of the State Hospitals. The laboratory was also to open its doors to all members of the profession desiring to avail themselves of its facilities. This was thoroughly impracticable as might well have been foreseen, for it gave an opportunity to divert the use of the laboratory to personal expedients. The director was fully justified in ignoring this proposed function.

In the report for 1895, the Commission announced the creation by statute of the "Pathological Institute of the State Hospitals," to be located in the city of New York, for the reason that besides being a medical center, there was located within a radius of sixty miles more than two-thirds of the insane in the State. It repeats the declaration that the Institute is established primarily for the benefit of the State Hospitals and "also to provide instruction in brain pathology and allied subjects for the medical officers of the State Hospitals, and to other members of the medical profession who may desire to avail themselves of the advantages afforded by this department."

During the year 1896, the Institute was located in the Metropolitan Life Insurance Building on Madison Square, and occupying fully the front two-thirds of the sixth story at an annual rental of more than six thousand dollars. The contention was that the location most central to the general hospitals, having an abundance of unobscured light, and sufficiently cool to permit work to proceed continually during the hot season was essential. In the following report (for 1896) the Commission announces the equipment and organization of the Institute, and sufficient progress "to demonstrate the wisdom of centralizing in one department the scientific investigations of all the hospitals in the yet obscure fields of pathology and causation of insanity." It is also here announced for the first time that the Institute is not to be confined to the study of pathology to problems of insanity exclusively, but that investigation was to be comprehensive and unite all the branches of science which could be brought to bear upon the scientific study of mental disease. The Institute therefore established the departments of normal histology, pathological histology, cellular biology, bacteriology, physiological chemistry, psychology, anthropology and comparative neurology, and the persons in charge of these several departments were known as associates, the whole being under the supervision of the director. There was also an associate who directly assisted the director in the administration of the Institute and a corps of lay employees, known as librarian, archivist, preparator, indexer, accountant, stenographer, janitor and janitress, several having assistants. The expense of maintenance for one full year, exclusive of equipment, but including rentals, approximated forty thousand dollars.[1] The attention of legislative committees having the preparation of appropriation bills was directed to the expenditures for the Institute by the financial statement required of the Commission. Fortunately, until 1899, the appropriation for the State Care of the Insane had been made by a direct tax on the people, collected as other State taxes, and the resultant was at the disposal of the Commission, under certain statutory restrictions. In 1899 this was changed to a definite appropriation included in the general tax levy, and precise sums were appropriated for the specific purposes of the department. In this appropriation, and in spite of the earnest protest of the President of the Commission, a definite sum was named for the Institute, although quite sufficient for its purposes. To obtain this, it was necessary for the Commissioner to appear before the respective committees of the Legislature, and state with all the solemnity of an oath and upon his honor as an upright public servant that the amount asked for was requisite, that no further economies were possible, that the Institute was being conducted solely in accord with the purposes of its creation, and that the Commission vouched for the proper and most economical expenditure of the moneys. The question being wholly a professional one, the lay commissioners turned the responsibility over to the medical commisioner, as a matter upon which they were incapable of judging. There are certain periods in man's experience where ignorance is bliss unalloyed.

It is not my intention to criticise the development or the administration of the Pathological Institute. I should be pleased to see its scope widened beyond the present, and comprehensive

[1] The appropriation for the year 1899 was thirty-six thousand dollars.

enough to apply all the sciences to the great purpose in view; but I am constrained to hesitate when the burden of State care is overburdened to carry on in a proper manner the elementary needs of the insane, to recommend its increase by the addition of scientific research not pertinent in a broad sense to that department of charity. During the summer of 1899, the Institute was practically vacated for the three hot months, and although the professional element of the organization may have continued research elsewhere, it was an incident which excited inquiry and criticism, in great part directed at that Commissioner who vouched for the economical expenditure of the appropriation. The Director was appealed to for an explanation and thenceforward until the present moment a constant effort has been sustained to determine how far and in what manner and to what purpose is the State justified in maintaining scientific institutions. If the Institute was created primarily for the benefit of the State Hospitals, it has failed in its purpose, for the State Hospitals have been a small element in its consideration, and for reasons promulgated by the director, in an exposition of the methods of research commended by him.[1] He has set forth many truths in a brilliant manner, but he has failed to take into full account the worth of clinical methods and their union with pathological research: and this is the criticism from the hospitals. The critics in the profession at large are numerous, but one class can be cancelled as having personal ends to serve. Others complain of the Institute as a close corporation, although maintained by the people for the people. They want a manifestation of the educational feature which was announced upon its establishment.

After a serious and painstaking consideration of the several matters which seemed to form a proper basis for inquiry, the Commission invited Dr. Edward Cowles and Dr. G. Alder Blumer (member of this Association) and Dr. Councilman of Harvard University to examine the scope and methods of the Institute, and report as to their value, the justification of the department of insanity in maintaining so comprehensive a scheme of research and the degree in which the present development of the Institute realizes the purposes of its creation. The questions submitted to this committee embodied the criticisms by the medical profession which were current during the past two years or more.

The speaker represents the unanimous sentiment of the Commission in stating that the sole motive actuating it in the inquiries thus far made to formulate a basis of justifiable procedure for the Institute, is the enhancement of the purposes for which the Institute was established—the spirit of the organic law—and to mark the border lines of "correlation" with the allied sciences, beyond which the State or at least the department of insanity should not go. Any other motive is foreign to the Commission, and any other claim is baseless. In the face of a determined opposition in the last legislature to cut out the appropriation entirely, the Commission made as strong an appeal as it was possible to make, or ever has offered, for the continuance of the Institute; but only partially succeeded, by receiving an appropriation of twenty thousand dollars, and even this is hampered by an embarrassing provision which prohibits any expenditure for rents. I was informed by the chairman of one of the legislative committees, that the arguments offered by the nearer representatives of the Institute, were almost sufficient to defeat the appropriation. The ordinary legislator is not capable of appreciating scientific arguments, and are better moved by personal assurances of supervising officials. Preachers of science are quite out of place in legislative halls.

There can be no denial that the Pathological Institute has accomplished some excellent work, and has in course of inquiry questions of prime importance to psychopathology. It is to be regretted that all research it has instituted cannot go on to completion, even should it call for the application of labor and material not in the jurisdiction of the department. The question is evidently not whether the investigations of the Institute are of value, but whether it is properly maintained by the State, and especially by the lunacy department. Furthermore, whether it is accomplishing all the functions for which it was created. The Commission has been convinced by the most trustworthy authority, that these questions bear a negative phase that calls for early and radical changes in policy. It is sincerely to be hoped that the present organization may be modified by cooperation of the director to harmonize with the convictions of the Commission and continue the more valuable researches in progress to the greatest possible degree; but that remains an open question. The teaching function should become a greater feature, a prime feature, perhaps. It is the conception of a Commisioner that the work of the Institute might be prosecuted in two departments, although under one director—*teaching* and *research*—each of which should be conducted by an experienced physician preeminently qualified.

The report of the Committee which served the Commission as well as the Institute, in its impartial investigation of the latter, is appended herewith (Exhibit A), but the time allotted for this paper does not allow reading it without a suspension of the rules. This report shows with what care all issues involved both in inception and development were considered, and the Committee has rendered an excellent service to the department, to the State and to science. For the scientific world is watching the experiment undertaken by New York, and abnormal tendencies would surely disrupt it in time; so that any effort which aids in restoring the Institute to a normal or appropriate standard, renders an invaluable service to science.

[1] "Correlation of Sciences in the Investigation of Nervous and Mental Diseases." Archives of Neurology and Psychopathology. Vol. I., 1898; by Ira Van Gieson, M.D.

I regret that it is not possible to announce at the present time the final determination of the Commission. It has endeavored to cooperate with the Director to conform the future of the Institute to the funds available, and the requirements of the service, scope and organization which in gross have been determined by the late inquiry but thus far without avail. A pathological department for the State Hospitals which is not administered in harmony with the State Hospitals, and subject in some degree to their respective requirements as interpreted by their Superintendents, is quite impossible as well as inappropriate. If the State desires to maintain a department of pure science, for science only, the medical profession in New York will cry Godspeed in one voice, and loudest of all the psychiatrists, but for the sake of all peaceful principles it should not burden the harmonious, hard-worked, conscientious and methodical lunacy department with it.

Exhibit A.

NEW YORK, February 5, 1900.

To the State Commission in Lunacy,
Albany, N. Y.

Gentlemen:—Pursuant to appointment by the State Commission in Lunacy, your Committee to report on the work and scope of the Pathological Institute of the New York State Hospitals met in New York City on February 3, 4 and 5, 1900.

Your Committee began its work by considering the history of the Institute, as contained in the reports of the Lunacy Commission and elsewhere, to the end not only that it should fully apprehend the purpose of the Legislature and the Commission in its foundation, but that it should also determine the degree to which the Institute had departed from that original and avowed purpose. It seems clear from the recommendation of the Commission in its Third Annual Report, for 1891, p. 272, that "a special pathologist for the use of all the State Hospitals" be appointed; and from that of the Sixth Annual Report, for 1893-4, p. 58, that the State should establish and maintain "a pathological laboratory or institute, under the direction of an accredited and competent pathologist which shall be maintained primarily for the State Hospitals;" and from the further suggestion in the Seventh Annual Report, for 1894-5, p. 104, that the proposed department of the State hospital system should "provide instruction in brain pathology and other subjects for the medical officers of the State Hospitals:" it seems clear to your Committee that the intent of the Commission was that the Institute should be a handmaid of the hospitals and subserve their needs in all matters pertaining to the scientific aspects of the work, especially in the domain of pathology and pathological anatomy in close alliance with clinical observation and research.

Your committee appreciates the fact that the Institute in the organization of its work must necessarily have been given freedom to develop it gradually, and experimentally in some respects: but, while recognizing the excellent quality of much of the work that has been done, which has received high and authoritative commendation, the committee thinks that the Institute has failed to fulfil the specific purpose for which it was established. Instead of undertaking the problems of mental pathology, in practical conjunction with the several hospitals, it has widened the field of its operations on the basis of the federation of the medical and biological sciences under the leadership of psychology. It has given too great prominence, in thus occupying the debatable ground of speculation, to the deduction of theories rather than to the study of the facts of science, on the principle that the work of the psychologist can explain living phenomena better than the pathological anatomist provided the psychologist has the general knowledge of the medical sciences. Your Committee approves academically of the correlation of the sciences, but believes that the attempt thus to correlate them is a departure from the function of the Pathological Institute.

It is the opinion of the Committee that the failure, from the point of view of the State Hospitals, has been due to too great diffusion of effort, whereas the aim from the beginning should have been to establish closer relations between the clinical and pathological aspects of the work. In a word, the function of the Pathological Institute of the State Hospitals is not the correlation of sciences but rather the correlation of the clinical needs of the physician with science. No estimate of these needs can leave out of consideration the duty of the State of New York to make adequate provision for instruction of the highest order for those who are called upon to minister to the insane, her dependent wards. As the State in its wisdom has taken wholly under its charge the care of the insane, their treatment and the use of clinical opportunities, these latter should be utilized in training to the fullest possible extent. The data of the Hospitals is the material upon which the Institute should do its work. It seems to your committee that it cannot be too strongly insisted upon that the teaching function of the Institute must ever be its warrant for existence and a generous State support. Research work upon the problems of insanity would naturally follow the carrying out of proper methods of instruction and cannot be successfully pursued without it.

The present Institute, your Committee believes, has taught methods not matter. If as a laboratory it had given the physicians in the service the opportunity to obtain accurate knowledge of the nervous system, the necessity for expansion would have been felt more and more in the direction of the clinical study of insanity. Such facilities could be better afforded in a central laboratory that should be in a closer contact with a State Hospital than is possible in its present location: they should include short systematic courses of instruction to small classes of officers from the medical service, detailed in turn for this purpose from time to time, with the subsequent guidance of their work in the Hospitals. Such an arrange-

ment would permit an appropriate coordination of the clinical with the various other problems, pathological, psychological, physiological, chemical, etc., that present themselves for solution, and thus furnish the natural stimulus to scientific work and promote the steady growth of a professional spirit. It is believed that, under competent guidance, such a laboratory, if it were connected with a small hospital to provide a sufficient variety of cases of insanity, would become a school of clinical psychiatry that would ultimately fulfil the great purpose that the Legislature and the Commission had in view in establishing the present Institute. Your Committee would therefore summarize its conclusions as follows:

1. The Pathological Institute should be maintained, but reorganized on a basis that shall have systematic teaching as its main function.

2. It should teach the fundamental principles whose study and application must lead to the clinical, anatomical and chemical research necessary for advancement in the curative and preventive treatment of insanity.

3. It should have as its director a physician who has had a training in clinical psychiatry, besides being a competent pathologist.

4. It should be located on property of the State, in a building of its own, as near to the metropolitan medical schools as is practicable.

5. As an essential of its teaching function its building should adjoin, or be a part of, a small hospital for the insane for the reception of acute cases and others appropriate for investigation.

6. Entrance into the medical service of the State Hospitals should be conditioned upon previous training in the Pathological Institute.

Respectfully submitted,

(Signed) Edward Cowles.
Wm. T. Councilman.
G. Alder Blumer.

CLINICAL MEMORANDA.

HIP-JOINT AMPUTATION.

By WM. D. HAMILTON, M.D.,
of Columbus, Ohio.

This paper describes five cases in which Wyeth's bloodless method of hip-joint amputation was used. Three of them were done by the writer, with one death and two recoveries. The other two patients were operated upon by my colleague, Dr. Chas. S. Hamilton, and both recovered. Of the last two, one had had a thigh amputation done by the writer, with early recurrence. The other case is of unusual interest and is cited in this connection for that reason.

Case I.—Mrs. J. E., forty-eight years of age, was seen with her physician, Dr. Aiken, at her home in Gallia County. She had had for the previous thirteen years a growth, involving the left knee and the lower part of the thigh. It had been pronounced sarcoma by two prominent surgeons of Cincinnati, who had advised amputation years ago, when she consulted them. Growth had progressed rapidly during the last year. Pain in the hip and knee had been severe. No evidences of tuberculosis were present in the patient or in her family history. There was not any history of traumatism. She had been crippled for several years. During the previous six weeks she had been confined to bed, and had become very anemic and feeble. Her extreme pallor and cachectic appearance suggested the possibility of deposits elsewhere. But metastases could not be found. The growth was fusiform in shape, eighteen and a half inches in circumference, and involved the knee and the thigh throughout most of its extent. Wyeth's method was employed August 8, 1895, at her home. After the operation was completed the pulse was 140 and weak. The femur, much softened, was found to be involved in a malignant neoplasm as far as the trochanter major. The patient died of shock five hours later in spite of the stimulation and the usual methods employed under such circumstances. The growth was sarcomatous.

Case II.—A. B., a carpenter by occupation, a resident of Columbus, was sent to Hawkes Hospital by his physician, Dr. Benjamin Lippett. He was fifty-six years of age. Seven years prior to his admission, he had fallen down-stairs and an injury to the thigh had resulted. Pain, disability and swelling had been very marked. The patient had attributed the tumor to this traumatism. While its progress had been very rapid during the three years prior to his admission, it had been especially so during the last three months. It extended from just above the knee so close to the hip as to leave very little healthy tissue below the articulation. It was rather firm to the touch, irregular in outline and was more apparent from behind than in front. The left thigh was twice as large as the right one. The malignant character of the tumor having been suspected, an exploratory incision was made under ether, April 14, 1899, when it was shown to be a sarcoma. Furthermore, it was found to have infiltrated the thigh so extensively that a hip-joint amputation was the only practicable expedient. This was accordingly done and he bore it well. There was practically no hemorrhage or shock. The wound was closed without drainage and he was discharged well in three weeks. There has been no recurrence.

Case III.—Miss W., aged sixteen years, of Washington Court-House, Fayette County, Ohio, was seen with the Drs. Ireland at her home, February 14, 100. Her grandfather had died of cancer of the lip. A tumor of the left thigh had been rapidly developing during the past six months. While at school, in the summer of 1898, she had struck her thigh against a desk and some swelling and lameness had followed. Severe pain was at times present. The growth enlarged the thigh

[1] Read before the Ohio State Medical Society, May 11, 1900.

to a point very near the hip-joint, having ascended higher on the outer than on the inner side of the extremity. Its malignant character had been suspected by her attending physicians. February 8, 1900, an exploratory incision into the growth showed its sarcomatous character and demonstrated that hip-joint amputation was necessary. This was done with a trifling amount of hemorrhage, but with some shock. A drain was employed and four hemostatic clamps were left in the wound, so inaccessible were certain deep vessels which did not readily admit of ligatures. Her convalescence has been quite satisfactory, and she now walks about on crutches. Her stoutness made neat coaptation difficult, and retarded the healing process.

Case II.—T. S., of Columbus, aged fourteen years, had been under observation since childhood for tuberculous osteomyelitis of the femur with sinuses. There were five children in the family of the patient, and he was the only member of it who was affected with tuberculosis. Incision, curettage of the sinuses, iodoform injections and tonics had been tried in vain. He had the waxy pallor which is often observable in sufferers from old tuberculous arthritis. He had persistent hectic and an abundance of albumin and casts in the urine, which was of low specific gravity. In spite of these unfavorable facts, he was subjected to hip amputation under ether at the Children's Hospital on November 27, 1899, by Dr. Charles S. Hamilton. Silk ligatures were used. He made a good recovery and is well to-day. The interesting fact is that prolonged suppuration, albumin, casts, low specific gravity of urine, profound anemia, with amyloid visceral changes, seemed to contraindicate amputation. It was done, however, with a full realization of the gravity of the situation. He is now well.

Case I.—Mrs. W. C. B., aged thirty-two years, of Columbus. Had been married eight years and had borne two children. No cases of malignant disease were found in the family history. At the age of seven years a mass as large as a hickory-nut was felt by her in the center of the calf of the left leg. The neoplasm grew steadily for twenty-four years, but within the previous few months it had progressed rapidly, so that the circumference of the middle of the leg was nearly twice as great as that of the other. The tumor, which pulsated distinctly, reached nearly to the knee, and a distinct bruit could be heard over most portions of it. There was some pain, but only within the past few weeks had locomotion been impaired. She was admitted to Hawkes Hospital and was etherized for exploration October 20, 1899. The malignant character of the growth was evident on section, and the thigh was amputated below its middle by the writer. Recurrence in the stump appeared within four weeks, necessitating amputation at the hip-joint, which was performed by Dr. Chas. S. Hamilton November 24, 1899. She convalesced rapidly, has since borne a healthy child, and is well to-day.

There is no doubt as to the great value of Wyeth's bloodless method where it is applicable. A well-appointed hospital is the proper place for its performance. There, too, shock can be more successfully combated, in case it should occur.

STUMP PREGNANCY.[1]

BY JOHN C. MORFIT, M.D.,
OF ST. LOUIS, MO.

IN August, 1897, M. A., aged twenty-three years, produced on herself an instrumental abortion. She was a working-girl in a department store, and to cover up suspicion had not remained away from her duties, but endured the pain while on her feet for a large portion of many days. This was the second experience of the kind she had had. She was referred to me the latter half of August, 1897. There were all the symptoms of pelvic inflammation: fever of a remittent type, pain and tenderness, especially in the lower abdomen, exaggerated on exertion or palpation. There was constipation and distention. There was, also, a muco-purulent vaginal discharge, very abundant, but not showing any gonococci—only the ordinary pus-producing organisms. The womb was soft, somewhat enlarged, very tender and red. In the cul-de-sac to the right a mass about as big as a hen's-egg could be detected, this was elastic, but did not fluctuate. The left ovary and tube could be felt, but were not pathologic. The mass on the right, I took to be a pyosalpinx, resulting from an infection incident to the criminal abortion.

Operation was decided on. The tube and ovary were removed, and about an ounce of pus escaped from the distorted and distended tube. At the time, I did not notice how far from the uterus I applied my ligature. Recovery was uneventful and rapid. The woman gained her accustomed robust health, except for the necessity of removing, six months after, one of the interrupted buried silkwormgut sutures, which was used to unite the fascia. This is a practice I have discarded, having substituted cumol catgut as a suture, and from which I have never experienced bad results in a considerable number of cases.

December 17, 1899, two years and four months later, I was called in the evening to see this same patient. She had a weak, thready pulse that I could not count; seemed worried: the lips were pale, the hands and feet cold, respiration quick and shallow with nostrils dilating at each respiratory excursion. She told me in slowly spoken words, that she had been two weeks overdue in her period and believed she was pregnant. She complained of the most intense pain in the right side from the shoulder to the hip, with especial reference to the right iliac region. She was so weak, nervous and excited that I did not make any attempt to examine thoroughly. There was

[1] Read before the Tri-State Medical Society of Iowa, Illinois and Missouri, April 3, 1900.

no mistaking hemorrhage, however, with such symptoms. I gave three-eighths of a grain of morphine and one-thirtieth of strychnine, hypodermically, and in half an hour, injected a quart of salt solution into the rectum. This was retained and the pulse soon became steady and was 120; the temperature was below normal. As she was quiet and calm, I left her and returned early in the morning. At this time I was able with less difficulty, but not without causing the patient considerable pain, to examine the abdomen, which was much distended, and tympanitic except low down posteriorly at the sides, where there was bulging and dulness. The pulse was now 110 and much stronger than on the previous evening, but the patient was too weak to stand anything and was kept at absolute rest. I repeated the salt solution per rectum and encouraged the patient to drink all the liquid possible. Her great thirst made her comply frequently. I then left her to prepare for operation, and arrange for her to be carried on a stretcher to a nearby hospital. Before I could barely inaugurate my plans, I was recalled and found the sufferer in a state of profound collapse. There was absolutely no radial pulse and that of the carotids was only perceptible. Listening over the heart, I could hear only a continuous whir, no well-defined beat interval could be detected. The patient was stupid and responded to questions in an indifferent manner. I had concluded from the first that this was a case of ectopic pregnancy and this second collapse was no doubt due to a recurring hemorrhage. At both times the woman's condition was such as to preclude the thought of an immediate operation. I could only hope to get her in condition where she could be taken to more favorable surroundings and anesthetized. Much to my gratification, I was able to get a favorable response to another quart of salt solution per rectum, and brandy, strychnine, nitroglycerine and morphine hypodermically.

By the next day at noon, or thirty-six hours after my first visit, I had her in the hospital, where she arrived with a pulse of 108, weak and thready, temperature 97° F. A pint of normal salt solution was immediately injected under each breast into the loose pectoral tissue. The same fluid was administered by the rectum, but not retained. Fortunately there was no vomiting, and the patient took a considerable quantity of fluid by the mouth. Pain was complained of and morphine and the heart stimulants were administered freely by the hypodermic method. At 8 A. M. of the second day in the hospital the pulse was 150, weak and compressible, and the temperature at the same time was 101° F. Both remained at this point, but the pulse became stronger and the pain greater in the afternoon. The pain and tenderness were now confined to the right iliac region and were most acute. The other abdominal symptoms were somewhat intensified.

At 5 P. M. I decided to risk an operation, although I had little hope of bringing the patient off the table alive. I made the incision in approximately the same line of the first operation of two years previously, and encountered several embedded silkwormgut sutures. There was a band of adhesion running from the median line outward and backward to the fundus of the cecum, just to where the vermiform appendix is given off. This two inches of adhesion resembled a thread of catgut.

I only noticed this incidentally. My first object, of course, being to find the bleeding-point and stop the hemorrhage. Hindsight being sometimes better than foresight, I recall that I endeavored to stop the hemorrhage and then found the bleeding-point. The belly was full of black, but sweet-smelling clots, and there was quite a quantity of fluid red blood. Knowing that I had at one time removed the right appendages, I sought the left adnexa, and felt my way through the clots, and applied a forceps to the proximate portion of the left broad ligament. With this pressure, I felt at ease to proceed to the toilet of the belly, and must have removed more than a gallon of clots and fluid blood. What was my surprise, on getting a clear field, to see that the oozing was from the stump of my old operation. There it was, about three-fourths of an inch long, and ruptured, presenting a fuzzy placenta to my view. Another forceps was applied to the right side, both tubes ligated close to the womb, and the distal portions removed. The abdomen was then filled with normal saline solution and sewed up with several layers of buried catgut sutures. The patient was returned to bed, and everything done to sustain strength and lessen the shock. Artificial respiration was kept up for over two hours, salt solution was injected per rectum, under the breasts, and into the cellular tissue of the thighs. Twenty hypodermic syringe-loads of brandy, besides strychnine and nitroglycerine were administered. For many hours the patient seemed to be only artificially alive, but our persistent efforts were finally rewarded by a gradual return of consciousness, and more emphatic evidences of real life. In four weeks the patient walked to her carriage and was driven home. Her recovery would have been perfect, except for the annoyance caused by her burning her legs with hot-water bottles. To-day she is a picture of perfect health and suffers none. In the ovary removed there was a large ruptured Graafian follicle.

This, I believe, is a variety of extra-uterine pregnancy which has never before been met with, and for that reason, I have named it *stump pregnancy*, it having occurred in the remains of a tube, the proximal end of which I had not entirely removed. The absence of the ovary and most of the tube on the right side, the occlusion by ligature of the stump, the presence of a normal ovary and tube on the left side, and a large corpus luteum being present in the only ovary, lead to but one possible conclusion. The fertilized ovum came from the left side, passed

through the left tube and the uterine cavity up into the remains of the tube on the right side, where it began to develop and finally ruptured the tube into the abdomen.

This upsets the theory, and heretofore generally accepted view, that ectopic pregnancy is due to some mechanical or inflammatory hindrance to the normal downward passage of the fertilized ovum. I believe this case proves quite clearly that the ovum may travel either down or up, or down and up, and, wherever an ovum may be fertilized in the ovary tube or uterus, it seems certain that it can come from either side and go everywhere and anywhere before anchoring itself preparatory to development.

3535 Olive Street.

MEDICAL PROGRESS.

Gonorrhea in the Female.—In the female the most vulnerable parts, says William Gardner (*Montreal Med. Jour.*, April, 1900), are the urethra, the fundus of the vagina, and the cervical canal. In no part of the genital tract do the gonococci penetrate beneath the epithelial layer, and this is least resistant in the child and senile woman. Pelvic aching, scalding of the genitals, and profuse, fetid, purulent discharge are suspicious. On examination the orifice of the urethra is swollen, red and pouting; if the discharge is not evident, pressure in the vagina on the urethra from within outward will reveal it. The vagina will often appear quite healthy when Skene's tubules, the ducts of Bartholin's glands, and the cervical canal are infected, but this combination is sufficient to establish the diagnosis. For clinical purposes the discharge may be spread upon a slide and stained with methylene blue, after being fixed by heating for a few seconds. To be certain of the diagnosis the biscuit-shaped cocci must be found in pairs inside the pus-cells. When the uterine body is involved it is bulkier, firmer, and more tender than normal, and it gives out a thin purulent discharge. The commonest complications are extension to tubes or ovaries; very uncommon is a cystitis or pyelitis. In the acute stage, rest in bed, bland diet, warm hip-baths, saline purgatives, and frequent soothing irrigation of the genitals, as by linseed tea, may be employed. In the chronic stage have a vaginal douche administered in the dorsal position, using 1-5000 permanganate of potash, bichloride of mercury, or formaldehyde, followed by a small quantity of warm water. With the patient in Sims' position, through a Sims speculum, apply a twenty- to sixty-grain solution of silver nitrate by a swab with pressure until every part is whitened. Follow this by a tampon of five-per-cent. ichthyol-glycerin. The urethra and cervical canal are best treated by instillation of Skene's tubules and the ducts of Bartholin's glands by injection of the solutions with a slender-nozzled syringe. In the uterine cavity local treatment must be avoided. In affections of the tubes and ovaries, many get well with long rest in bed, good nursing, and symptomatic treatment; and if operation be inevitable, the longer the interval since the acute symptoms have subsided, the more favorable will be the course of the case.

Modern Dietetic Preparations.—Whenever anorexia exists or deglutition is rendered difficult, owing to stomatitis or diminished saliva or to the presence of functional or organic disease of the alimentary tract, the use of artificial food preparations is indicated. On account of the increasing number put on the market, J. Marcuse (*Therap. Monatshft.*, May, 1900) finds it advisable to indicate the value of the most important ones. Perhaps the first preparation was Liebig's extract, but this, owing to the high percentage of extractives and mineral salts, is more stimulating than nutritive. Of meat-juices, Valentine's is too expensive and contains but five per cent. albumin in comparison with Puro which contains thirty-one per cent. Most other meat-juices are of little value. Peptone preparations were next advocated, but, since physiology has shown that they are of no more value than ordinary albumin, their use has become more and more restricted, especially since, when long continued, the peptone will irritate the mucous membrane. Somatose, with its fifty-one per cent. of albumose, was then expected to solve the problem, but the entire absence of extractives and the development of diarrhea, vomiting and even loss of weight after prolonged use, have disillusioned all enthusiasts. A step in the proper direction was taken when the value of phosphorous containing proteids was appreciated. Casein may be considered the type of these and is the base of eucasin, nutrose, samose, sanotogen, plasmon, eulactol and others, which, besides their cheapness and high concentration, are readily soluble and almost tasteless. Other valuable preparations, among which may be mentioned mutase, tropon and aleuronat, contain vegetable proteid. In conclusion, the author points out that the importance of albumin in foods is generally overestimated, since but two ounces daily are needed if carbohydrates and fats are present in sufficient amount. Another mistake that is frequently made is that the importance of water and salts as integral parts of food is often underrated.

Treatment of Gastric Ulcer.—The mortality of gastric ulcer has been lessened by appropriate treatment from about fifty per cent., as estimated by Bimton, down to about ten per cent. at the present time. B. Reed (*Internat. Med. Mag.*, May, 1900) suggests that in every case showing marked hydrochloric-acid excess, the danger of ulcer should be appreciated and the condition treated and subsequently guarded against. The indications to be met in the cure of the disease are (1) to put the stomach at complete rest; (2) to reduce the hyperchlorhydria; (3) to allay the pain and vomiting; (4) to preclude or arrest hemorrhage. The patient should be kept in bed

for three weeks at least and for one week fed exclusively per rectum. Hot poultices or compresses may also be used over the epigastrium. A clyster of salt and water should be used as a cleansing agent before the nutrient enemas are administered. These may be given two to four times a day, and need not consist of predigested food, the following being very efficacious at times; good fresh milk, freshly expressed beef-juice, raw eggs, solutions of sugar and also of very thoroughly cooked starch. A pint of salt should be added to each enema. Ewald recommends two to three eggs beaten up with a tablespoonful of cold water, then a tablespoonful of prepared cereal, dextrinized by heat, is boiled with a half tumblerful of twenty-per-cent. solution of grape-sugar and a wine-glassful of claret added. When lukewarm, stir in the eggs and add fifteen grains of salt. When the contents of the bowel become acid beef-tea should be given instead of milk and the sugar. Feeding by mouth should be begun with milk and lime-water, equal parts, giving at first a tablespoonful every half-hour and then increasing the quantity and the length of intervals. Barley-water, lightly boiled or poached eggs, slightly salted, and calf's-food jelly may be slowly added to the regimen. Vomiting may be relieved by pellets of ice and extreme thirst should be allayed by frequent sippings of cool water. Persistent pain and burning is usually due to excess of hydrochloric acid and is relieved by half- to one-dram doses of sodium bicarbonate. In stubborn cases forty to sixty grains of bismuth subnitrate in a draught of water may be given one hour before each feeding. When constipation results it is best relieved by enemas of olive oil. Hematemesis seldom occurs when on such treatment, but when it does appear the patient is immediately put to bed, an ice-bag applied to the epigastrium, and ice given by mouth. Ewald records having checked hemorrhage by washing the stomach out with ice-water, but this is very dangerous. Large doses of bismuth in lime-water, with one drop of carbolic acid and flavored with spirits of chloroform and compound tincture of cardamon, are often very valuable.

Therapy of Anthrax.—Contrary to some clinicians who advise expectant treatment in true carbuncle, A. Strubell (*Münch. med. Woch.*, May 8, 1900) recommends energetic measures, consisting in the application of very hot poultices (up to 145° F.) to the local lesion and the injection of a three-per-cent. solution of carbolic acid into the gangrenous tissue. Bacteriological examinations showed a gradual disappearance of the bacteria in the tissues with above methods. The patients can readily stand the high degrees of heat, owing to anesthesia, and carboluria does not follow.

Roentgen Rays in Aneurisms.—G. Kirchgaesser (*Münch. med Woch.*, May 8, 1900) speaks well of the value of the fluoroscope in diagnosing aneurisms of the aorta. The aneurisms usually throw a shadow beside the heart which can be seen to enlarge in all directions with each heart-beat. This picture must not, however, be regarded as pathognomonic, for, in a case examined by the author in which the shadow was well-defined and the pulsation marked, the post-mortem examination disclosed the presence of carcinoma of the cardia with extreme dilatation of the esophagus above, thus simulating aneurism. It is, therefore, desirable not to rely too much on the Roentgen-test, especially when the physical signs are poorly developed.

Vaccination and Variola in Pregnancy.—In vaccinating pregnant women M. Ch. Vinay (*Gaz. Hebd. de Med. et de Chirurg.*, May 3, 1900) points out the greater predisposition of these patients to infectious diseases in general and recommends great caution, especially when the operation is to be done upon the legs where the venous congestion may lead to a rapid spreading of any complicating infection. The protection afforded by the vaccination will also extend to the infant.

Dysmenorrhea Membranacea.—The following conclusions are given by Kollmann (*Wiener klin. Rundschau*, April 29, 1900) as having been arrived at in his experience as gynecologist regarding dysmenorrhea membranacea: (1) Membranous dysmenorrhea has no connection or dependence upon pregnancy or abortion. (2) It does not necessarily cause sterility. (3) It may end in spontaneous cure. (4) The dysmenorrheic membranes have nothing to do with inflammation of the uterine mucosa. (5) The fibrinous membranes are to be regarded purely as dysmenorrheic in character. (6) Unless examined closely these may be mistaken for blood-coagula or for the products of a croupous inflammation. (7) These fibrinous membranes are produced by a necrosis due to hemorrhage and exudation into the connective tissue of the uterus.

Symptomatology of Pleural Endothelioma.—Although recent advances in pathology have made it probable that endotheliomata are to be classified among epitheliomatous growths, the clinical history of the patients is often not so definite and, therefore, the diagnosis is not always possible. An interesting case is cited by A. Schultze-Vellinghausen (*Münch. med. Woch.*, May 8, 1900). He states that the diagnosis is generally made only in the advanced stages of the disease. A hemorrhagic fluid obtained by aspiration is, perhaps, the most constant and valuable sign, for, although this also occurs in phthisis, the absence of confirmatory evidences of phthisis and, more particularly, the large amount of the fluid and the rapid refilling of the pleura, speak for tumor. Large, polygonal cells in sheets, with large nuclei, are not rare in the fluid and can be distinguished from normal endothelial cells by applying a very dilute iodine solution, which in case of tumor, will color the cells brown. The sputum, too, may contain these cell-aggregations. Other valuable points are the de-

velopment of papillary excrescences over the puncture-holes and the sensation of increased resistance which is noted on penetrating the dense tissue into which the infiltrated pleura is converted. The irregularity of the area of flatness is also suggestive. On the other hand, the greater distention of the affected side of the chest; the displacement of the adjacent organs, pains, absence of fremitus and voice and breathing, afford no help. Concerning etiology but little can as yet be said, but it is significant that in many cases some trauma to the chest wall precedes the growth.

Advantages of Aspirin.—From a study of a large number of rheumatic cases, K. Manasse (*Therap. Monatshft.*, May, 1900) is inclined to decide favorably as to aspirin. In all the acute cases there has been a prompt disappearance of symptoms, while in the subacute or chronic cases the patients were always made more comfortable with this than with other drugs. Daily doses of 45-60 grains do not injure the heart or other viscera nor are nausea and tinnitus ever caused, although they almost invariably follow the prolonged use of the salicylates.

Natural Sulphur-Water in Gall-Stones.—A. Winckler (*Therap. Monatshft.*, May, 1900) speaks very highly of the power possessed by sulphur-waters to increase and dilute the bile and thinks that in this respect they greatly excel the alkaline springs. The patients may drink the water at home or, preferably, should spend a few weeks at some watering-place where strong sulphur-springs exist. The cure should be continued for some time after the expulsion of the stones. The author also draws attention to the excessive ingestion of eggs as a possible etiological factor in causing gall-stones, since the yolk contains as much as one-half per cent. of cholesterin. Bread, also, should be used with moderation.

Liver Abscess and Appendicitis.—E. Loison discusses this subject (*Révue de Chirurgie*, 1900, pp. 522). There are meager statistics on this point, the following being the only reliable data. Reginald Fitz in 257 appendicites found 11 examples of suppurative phlebitis and hepatitis; Langheldt in 112 autopsies of appendicitis shows 4 cases of phlebitis and thrombosis, 2 of abscess of the liver, 2 of suppurative hepatitis, 2 of perihepatitis; Einhorn reports 100 appendicular postmortem examinations and found 6 complicated by infectious embolism of the portal vein, accompanied by pyophlebitis and by secondary abscess of the liver; Coley among 200 cases of appendicitis notes 2 of the liver and 1 of subphrenic abscess. Scattered through literature are other isolated cases beginning with 1849, when apparently the first reported instance was given. The avenues of infection may be the biliary canals. There is one well-established case of this on record. The usual ways of involvement are along the hepatic artery, the portal vein, the lymphatic system, and, by direct contact the peritoneum or retroperitoneal cellular planes. The arteries are the sources of deposit only as part of a general pyemia. The portal vein carries the germs directly in its current or as emboli following pyophlebitis with or without thrombosis. The lymphatics may connect immediately with those of the rest of the intestinal tract going to the liver, or by adhesions of the appendix with the parieties finally anastomose with the channels there and thus indirectly reach it. The pus may enter the mesentery of the appendix, burst through its base into the retrocecal cellular tissue and behind the colon in the retroperitoneal planes work upward. The causes of hepatic involvement are either unusual virulence of the germs or temporary depreciation of resistance, local and general. The ascent of the right lobe and fixation of the diaphragm as shown by the radioscope are excellent aids to definite diagnosis and often the site for exploratory puncture can be located. The prognosis is usually unfavorable in virtue of the combined appendicular and hepatic invasions. Multiple hepatic abscesses are almost always fatal. The prophylaxis is concerned with the early diagnosis and treatment of the appendicitis. Free evacuation and ample drainage of all the foci are the only treatment.

Trachoma.—Trachoma is such a common disease and its cure so difficult that the suggestions offered by N. B. Jenkins (*N. Y. Med. Jour.*, May 19, 1900) in regard to the cause and treatment of the condition are especially interesting. He believes that the probable cause of uncomplicated trachoma is chronic irritation or spasm of the ciliary muscle—accommodative asthenopia. This usually comes from errors of refraction, but it may be caused by excessive use of the eyes. Irritation or inflammation of the conjunctiva from filth, dust, or infection causes irritation or spasm of the ciliary muscle and trachoma may result. Trachoma is not especially contagious, but usually becomes complicated with infection and parasitism. It appears in several members of the same family oftentimes because its chief cause, ametropia, is hereditary. Irritation or spasm of the ciliary muscle from ametropia frequently affects an entire family, and may be caused by very low degrees of ametropia. Any inflammation or irritation of the conjunctivæ may cause blepharospasm, which is probably a factor in trachoma since it causes friction and congestion of the eye and its appendages. Perfect rest will usually give relief to trachomatous eyes and is the chief indication in this condition. Instillations of atropine, together with the use of bandages or cataract shields during the day, are of great use. Before bandaging a weak iodoform ointment may be applied to conjunctivæ and lids. At night the protection should be removed and the patient kept in the dark. Properly-fitting glasses should be used when the eyes are not at rest. Massage is very beneficial and is practised every week or so by rubbing the granulations lightly with a strabismus hook. Trachoma for-

ceps destroy valuable tissue. The benefit derived from bluestone, alum and lunar caustic the author believes is due to the massage or the result of the rest the eyes receive on account of the pain induced.

Condition of Blood in Cancer of the Stomach.—In carcinoma of the stomach the patient usually presents such a degree of anemia, and may even simulate so closely the appearance of a pernicious anemia, that the blood-examination becomes an important feature. W. Osler and T. McCrae (*N. Y. Med. Jour.*, May 19, 1900) have given the results of the examination of the blood in fifty-nine cases of cancer of the stomach. The average number of red corpuscles was 3,712,186 to the cubic millimeter, a high blood-count since many of the cases were far advanced or cachectic. There were only eight cases below 2,000,000 and only two had a count below 1,500,000. One of these last had a large ulcerated area. These figures are important in differentiating from pernicious anemia. T. P. Henry has well said that in stomach cancer the diminution in red corpuscles does not keep pace with the cachexia, while in pernicious anemia the cachexia holds no pace with the oligocythemia. He has never seen a fatal case of pernicious anemia in which the red corpuscles were not below 1,000,000. Improvement in the blood condition was not common under medication and this may be of diagnostic importance. On the other hand, no marked loss in the condition was seen. Poikilocytes and normoblasts were found in many of the severe cases, but in no instance was a typical megaloblast seen. In fifty-two cases the hemoglobin averaged 46.9, giving a color index of 0.63. Nearly all those cases with lowest records showed marked ulceration. An examination of the white blood-corpuscles gave very little information. Neither ulceration, nor the presence of metastases, nor the situation of the growth, nor the relation of the temperature seem to have any constant effect upon the number of leucocytes. Differential counts of leucocytes proved to be unimportant and no myelocytes were found. The absence of a digestion leucocytosis has been held to be suggestive of cancer of the stomach. In this series, an accurate record was obtained in twenty-two cases, of which ten showed the presence of digestive leucocytosis and, therefore, the presence or absence of this condition would appear too uncertain to be of any diagnostic value. In a few cases of cancer the sallow, lemon tint of the skin, so characteristic of progressive pernicious anemia, was present. The authors conclude that (1) in a doubtful case a blood-count below 1,000,000 red blood-corpuscles is strongly in favor of pernicious anemia; (2) while normoblasts are present in all severe cases of secondary anemia, megoblasts rarely, if ever, occur in cancer of the stomach; (3) the number and kind of leucocytes present seem to be of no value in the diagnosis of this condition.

Operation in Uterine Cancer.—H. A. Kelly (*Jour. Am. Med. Assoc.*, May 19, 1900) says that in every case of cancerous uterus the entire organ must be removed, and no partial operation can ever be justifiable. In all cases in which the uterine body is involved, the tubes also must be removed. On the vaginal side one must cut away at least one inch from the edge of the growth, for often the neoplasm extends under the vaginal mucosa without causing perceptible infiltration or change of color. Portions of the bladder and rectum must be sacrificed if necessary. Nearly all cases of bowel involvement are associated with extensive lateral involvement. Cervical cancer extends by contiguity. Glandular metastasis is unusual in the earlier operable stages. The results of operation are sufficiently good to justify operation. The old method of shelling out the uterus only, is most liable to be followed by a recurrence. It is of greatest importance to pass catheters into the ureters to mark them out clearly during operation. Dr. Kelly's favorite operation consists in the following steps: Thorough curettage; circular division of vagina one inch below the diseased area; separation of bladder from vagina up to the vesico-uterine fold, which is widely opened, a wide opening of posterior cul-de-sac. The fundus is pulled forward through the anterior opening, the uterus bisected and then each half is divided transversely into two sections which are removed with the adnexa in such order that the most involved quadrant is removed last, since in this way more room is given for the complete extirpation of this most dangerous portion. If the ureter is involved, it should be resected and anastomosed into the bladder further back, and the extirpation completed, going all the way out to the pelvic wall if necessary. Drainage is to be used according to necessity.

Raynaud's Disease in the Insane.—Superficial symmetrical gangrene, writes J. E. Courtney (*Jour. of Nerv. and Ment. Disease*, May, 1900), is most frequently associated with mental disease. There may be a shallow but actual gangrene on some part of the extremities, with detachment of the skin and gradual healing of the raw surface left. The loss of tissue is much less than the extensive blackening of the surface would lead one to expect. Abortive attacks also occur in which small areas of fingers or toes show pallor, coldness, and slight anesthesia without gangrene; or the skin of the tips of the fingers or the back of the hand may darken, shrink, and peel as in severe sunburn. In these conditions the indications are rest, hygiene, tonics and attention to the nutrition, with, locally, warmth and scrupulous cleanliness.

Tuberculosis in Boston.—The Boston Board of Health has classed tuberculosis as contagious, and requires reports of cases of this disease from physicians. During the past five years deaths from consumption in Boston have been about double the combined mortality from scarlet fever, diphtheria and typhoid fever.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

J. RIDDLE GOFFE, Ph.M., M.D., Editor,
No. 111 FIFTH AVENUE, NEW YORK.

SATURDAY, JUNE 2, 1900.

THE AMERICAN MEDICAL ASSOCIATION AND THE ATLANTIC CITY MEETING.

ON Tuesday next the American Medical Association will convene at Atlantic City for its fifty-first annual meeting. Those who attended the meeting at Columbus last year have scarcely yet recovered from the feelings of discomfort endured during that oppressive weather from which no relief could be found and are welcoming with pleasant anticipation the brief sojourn by the sea. The invigorating ocean breezes of Atlantic City are proverbial, but the *Association Journal* has reached the climax of commendation in its prospectus of the meeting when it says that the air is such that we shall all feel when we take it in that we are ambassadors at the Court of St. James. A courtly grace and dignity may, therefore, be expected to sit upon every man's brow and the amenities of high diplomacy characterize the meeting's transactions. "Ambassadors" will be as thick as Colonels 'fore de war.

Thorough business principles and methods seem to have characterized the preliminary arrangements and everything gives promise of a large attendance and a most successful meeting. The programs of the various Sections show evidence of careful forethought in securing for discussion the live topics of the day and placing the subjects in competent hands. More and more attention is being given each year to the scientific work and the quality of the transactions is attaining such excellence that the question of embodying them in a volume of more permanent form than is afforded by the weekly journal is worthy of consideration.

The addresses also are of a high order and engaging character. These will be presented in next week's issue of the MEDICAL NEWS as well as a concise and interesting report of the scientific and business proceedings.

THE NEW YORK PATHOLOGICAL INSTITUTE.

IT is no secret to the members of the profession interested in scientific research that for some time serious friction has existed between the State Commission in Lunacy and the Pathological Institute. The director of the Institute claims that he has been subjected, by the Commission, to petty annoying criticism the object and end of which he could not understand but which interrupted and interfered materially with the progress of his work; that the Commission was unable to, or at least did not, make clear to him in any definite practical way what it wanted, except to give him the impression that it was bent on putting a stop to his original scientific research and determine to reduce the Institute to a clinical-laboratory appendage to the State Hospitals, with a teaching function.

The establishment of the Institute was the first, definite, well matured and efficient endeavor ever put into practical operation to solve the problem of insanity. Naturally the MEDICAL NEWS, as well as all friends of progress along these lines, were intensely interested in the success of the enterprise. When it was assailed therefore the MEDICAL NEWS opened the question before the court of last appeal in medical scientific matters—the medical profession, and called upon Dr. Wise as President of the Commission to present his case. It has required some persistence on our part to induce him to meet the issue and we are therefore gratified at presenting in our columns this week what in legal phrase we may denominate "The Commission's Brief."

Unfortunately there is running through it all, and especially pronounced in the letter to the editor, a strong undercurrent of personal feeling, which is greatly to be deplored. The essen-

tial fundamental principle of the Institute and the hopes that its success had aroused are in danger of extinction. But this aside, the burden of the complaint seems to be that the Institute has departed from the original and avowed purpose of the legislature and of the Commission in its foundation. There may be just ground for honest difference of opinion on this point. The fact can only be determined by a careful résumé of all the annual reports bearing upon the subject and the wording of the law. In addition to what Dr. Wise has given we have space for only one quotation from the Seventh Annual Report of the Commission as follows: "The legislature at its last session authorized the establishment by the Commission of a department for the special study of mental pathology and allied subjects * * * * the aim being to provide for the exhaustive study of the causes and conditions that underlie mental diseases, from the standpoint of cellular biology, which is now elevated to the dignity of a special science; also to provide instruction in brain pathology and allied subjects for the medical profession, especially alienists and neurologists, etc." There was a dominant idea in the minds of most of the Hospital Superintendents, of which Dr. Wise was formerly one, that the Institute was founded for the purpose of simply examining morbid specimens and chemical compounds sent to it by the different State Hospitals. They have been unable to reconcile this with the broader conception of general psychological research. This is demonstrated by the fact that the Superintendents have sent to the Institute for examination, specimens of vanilla and lemon extracts, soap powders, butter to be tested for oleomargarine, water, sewer and sludge contents and finally bed-bug exterminators. Against the last the chemists did rebel. The Institute made the analyses but at the serious delay of work on epilepsy and other subjects. This has been a prominent cause of dissension.

One criticism prominently urged is that the hospital staffs and Institute do not work in harmony in the matter of instruction. During the first three years of its existence the Institute instructed sixteen men of the staffs of the various hospitals. During the winter just passed the Director solicited men from the staffs of ten of the hospitals to be sent for instruction at the Institute. Without exception "hospital duties" prevented a single member of any hospital from responding to the call. If the system of work in the hospitals prevents the members of the staffs from attending instruction at the Institute certainly the Institute ought not to be held responsible. Even among the sixteen men who came, in former years, only one is now following out his scientific work in the hospitals; the others have resigned or been so overwhelmed with their routine work that they were forced to give up their investigations. The system of the State Hospitals and the State care of the insane is and must be, under the present system, a perfunctory one. The daily life of the physicians in these hospitals shows that they cannot give any time for scientific study of the patients under their care. The senior assistant makes his morning rounds, accompanied by his junior assistant, among 300 to 400 patients, few if any of whom he knows by sight. On this formal round there is time to chat with only a few. Before leaving the ward he must inspect clothing, bedclothes, general housecleaning and sanitation, examine reports and requisitions. He may then be obliged to follow patients who have already gone to the exercise grounds, hastily con them over, deliver instructions to attending nurses, arrange the hours of the nurses, who shall be on duty, who off, etc. During the interval before lunch if any patients are sick with intercurrent diseases they must be seen and prescribed for. During the three hours after lunch he must sit in the office to receive and talk with friends of the patients, make notes of what they say, who they are, etc. The junior spends his time writing out the long histories, making notes and copying them into the almost endless history books. The Superintendent is general manager and hotel keeper. These men are all sad victims of "a system which molds them into methodical machines with a maximum of routine output and a minimum of intellectual activity." No wonder that clinical study of the insane in the State Hospitals has proved sterile in finding the causation of insanity and presents no scientific basis for treatment. Small wonder that "hospital duties" prevent the staff from taking instruction at the Institute.

The scientific side of psychiatry still lags behind the other branches of medicine and will continue to do so until scientific men are permitted to work out unhampered the problems underlying mental disease. The insane hospitals are closed to them because the system there in vogue prevents scientific research. The physicians there are overwhelmed by executive routine and cannot work out the problem. Such knowledge can only be wrenched from Nature by long, patient,

persistent research on the part of trained scientists. Such are the men at work in the Pathological Institute. It was expected by the Commission which founded the Institute that at least ten years would be required to accomplish any tangible results looking toward the establishment of a definite pathology of insanity. The scientific work already accomplished by the Institute has attracted the favorable notice of the scientific world and this too in spite of the fact that a large portion of the time has necessarily been taken up with the details of organization and equipment. It is now going forward with its work along numerous lines of enquiry that give promise of great and far reaching results. If we mistake not, the voice of the profession will be: Hands off, give it time.

THE AFTERMATH OF THIS YEAR'S GRIP.

WE have had this year, as in every year since 1890, a recurrence of the grip epidemic. The disease, therefore, may fairly be said to have established itself as an endemic in the Western world.

Each year has seen the development of certain special features of the disease. It has never come back in quite the form it presented at its previous visitation. This year has been no exception to the rule and although the season is now well advanced we have not gotten entirely beyond the malevolent effects of the disease.

Nervous symptoms have been the special complication and they have sometimes seemed to demand the presence and activity of other causative agents in addition to Pfeiffer's influenza bacillus, although they have always subsided as soon as the more pronounced grip symptoms were under control.

In children there has been a special liability during the year to the development of otitis media, which has often required a resort to the mastoid operation. This complication has been noted before, but not with such frequency as during the present year. Another feature of the past winter's influenza in children has been its proneness to cause very high temperatures. It has not been an uncommon occurrence for the temperature to reach 105° in cases of simple grip. These febrile movements have at times been very irregular or intermittent with almost daily drops to subnormal temperature. In adults as well as in children there has been a marked tendency to the development of cutaneous eruptions. Cutaneous complications have been noted very generally also in England. These skin manifestations have usually been of the character of nervous cutaneous lesions, the multiform eruptions which are caused by the presence of toxins in the circulation, whose action is mainly on the trophic fibers in peripheral nerve-endings. Mental symptoms and sequelæ have also been a distinct feature of the disease. Many patients have labored under a depression during the course of the disease that seemed utterly disproportionate to the severity of their influenza infection. In some of these cases neurasthenia and in others melancholia have remained during a prolonged convalescence; the whole clinical picture being that of a severe, protracted and exhausting disease rather than what seemed at first a comparatively mild affection.

The phases of grip during these years of its prevalence form very interesting data for the natural history of the disease. There is undoubtedly some rule of influence in the meteorological conditions that obtain during certain seasons which it is quite within the realm of carefully compiled statistics to solve. The problem appears upon its face so complicated as to be hopeless, yet it is probable that some of its simpler elements would yield readily enough to patient investigation and the collation of weather conditions and types and quality of virulence of the disease during special seasons. Successful work in this line would be practically ground-breaking and would doubtless prove suggestive to a host of investigators.

ECHOES AND NEWS.

NEW YORK.

City Hospital Nurses.—The twenty-fifth annual commencement of the New York City Training School for Nurses was held in the chapel on Blackwell's Island May 31st.

The City's Vital Statistics.—There were 15,314 deaths in New York City during the last quarter of 1899, according to the Health Board's report. The death-rate was 17.25, based on the following borough ratios: Brooklyn 16.08, Queens 15.95, Manhattan 17.17, Bronx 22.26. The high death-rate in the Bronx is largely due to the many deaths in city institutions there of inmates transferred from Manhattan. There were 141 suicides during the quarter.

Addition to Woman's Hospital.—A four- and five-story addition has been planned for the New York Medical College and Hospital for Women, at 19 West One Hundred and First Street. The present structure will be raised one story, so as to conform with the addition. The cost will be about $43,500.

Beth Israel Hospital.—The corner-stone of the new Beth Israel Hospital at Cherry and Jefferson Streets was laid on May 27th. Great numbers of people were present. Mr. Guggenheimer said that ten years ago "the race which realized that love of humanity transcends in its strength and beauty any theories of theology established this hospital."

Contagious Diseases.—For the week ending May 26, 1900: Measles, 577 cases, and 22 deaths; diphtheria, 249 cases and 42 deaths; laryngeal diphtheria (croup), 6 cases and 3 deaths; scarlet fever, 114 cases and 10 deaths; smallpox, 4 cases; chicken-pox, 18 cases: tuberculosis, 211 cases and 181 deaths; typhoid fever, 17 cases and 6 deaths; cerebrospinal meningitis, 7 deaths; totals, 1196 cases and 271 deaths.

Association of Military Surgeons.—The ninth annual meeting of this organization has been held during the past three days at the Academy of Medicine. The principal subjects for discussion were: Examination of Recruits; Camp Sanitation; Rations; Transportation of Wounded; Field and Service. Many of the papers read embodied the results of service in the field during the Spanish-American war, and the various insular campaigns which have followed it.

Robbed Doctor's Office.—Three hundred dollars' worth of instruments were recently stolen from the office of Dr. James W. Harris in Brooklyn. They were, however, all recovered. A man called on the afternoon of May 26th and asked for the doctor. He was not in, and the man said he would wait. A few moments later he was discovered filling his pockets from a drawerful of surgical instruments. He was subsequently caught and imprisoned.

Smallpox from the South.—There were on May 28th two cases of smallpox at Haverstraw, three at Tarrytown and one at Dobbs Ferry, all of negroes who came to this State from Newport News. Secretary Smelzer, of the New York State Board of Health, has written to the Virginia State health authorities, requesting that more stringent measures be taken in quarantining smallpox so as to prevent its spreading over adjoining States.

Roosevelt Hospital's Needs.—In the twenty-eighth annual report of the Roosevelt Hospital, which has just been published, it is stated that the sum expended for the hospital's support, $152,677.95, including repairs and improvements, was $7,918.68 greater than that for the previous year. During the year 2,752 patients, of whom 411 were paying patients, were treated; 65,465 visits were made to the Out-Patient Department, a falling-off of 6,228 from the records of the previous year. An additional endowment of $500,000 is urgently needed to care properly for the present group of buildings.

Dr. Shaffer Corrects a Statement.—The New York State Hospital for the Care of Crippled and Deformed Children has been incorporated, and Dr. Newton M. Shaffer has been made the institution's surgeon-in-chief. It has been stated that "all surgical and medical officers of the hospital except the surgeon-in-chief shall render their services gratuitously." Dr. Shaffer calls attention to an error in this statement. He has absolutely declined to receive any salary. The Doctor further informs us that "a fund of nearly $5000 (in which I have had the privilege of joining) has been raised from private sources as supplemental to the money appropriated by the State."

Death of Dr. Otis.—Dr. Fessenden Nott Otis, formerly of this city and of world-wide reputation among medical men, died in New Orleans on May 24th at the age of seventy-five years. He was a frequent attendant at the clinical lectures in the New Orleans Charity Hospital, where he caught a severe cold which developed into pneumonia. From this disease he recovered but a carbuncle then developed from which he died. Dr. Otis was Clinical Professor of Genito-Urinary Diseases in the College of Physicians and Surgeons from 1870 up to 1890, when he resigned and went abroad. He was graduated from the New York Medical College in 1847. He was the author of books, articles and pamphlets on medical and other subjects, and he was the inventor of a number of instruments, especially for use in genito-urinary work.

PHILADELPHIA.

Woman's Medical College.—The Chair of the Principles and Practice of Surgery and of Clinical Surgery has recently been made vacant by the resignation of Dr. Thomas S. K. Morton.

Jefferson College.—Dr. H. W. Stelwagon, Clinical Professor of Dermatology, has recently been made an honorary member of the National Dermatological Society of Italy.

Public Baths.—The second annual report of the Public Bath and Wash-house on Gaskill Street shows a total of 34,680 bathers and 1487 washers during the year. Indications point to the institution becoming self-supporting in a few years.

Rural Sanitation.—In an address before the Health Authorities' Association at Mechanicsburg, May 24th, Mr. W. H. Allen of the University of Pennsylvania stated that local supervision of rivers was futile in obtaining pure water supply for cities. Cities should seek to abolish river pollution rather than to mitigate it by filtration, etc. Inspectors under the direction of the State Board of Health should patrol the rivers of the State.

Health Report.—Deaths for the week ending May 26th were 424, a decrease of 111 from those of the previous week and an increase of 40 over the corresponding week of last year. Contagious diseases: Diphtheria, 88 cases, 16 deaths; scarlet fever, 50 cases, 2 deaths; typhoid fever, 66 cases, 6 deaths. Influenza was the cause of 4 deaths.

Medical Examinations.—Dr. S. Weir Mitchell, in a recent communication to the *Philadelphia Medical Journal*, expresses himself as strongly in favor of an oral examination being added to the present test of the State Board of Examiners. It is unfair to subject men practically trained to only a written examination. For this reason practical tests should also be made, as questions upon a dissection, the description of microscopic slides, a single urinary examination, etc. It is essential that the State Board by degrees improve its tests.

Pathological Society.—At the meeting held May 24th Drs. Pearson and Ravenel exhibited a lung containing a dense growth of the aspergillus fumigatus. The specimen had been removed from a cow which died six months after showing symptoms, there being almost continuous cough for the last two months. The lung was markedly emphysematous and the bronchi were involved. Portions resembling partially-organized hemorrhages proved to be networks of mycelial threads. In the discussion which followed Dr. McFarland mentioned the fact that the specimen was presented by the first veterinarian admitted to the Society. The wisdom of admitting such members is evident from the benefit to be derived from comparative pathology. Dr. McFarland then exhibited cultures of the plague bacillus. Some cultures of the bacillus are pathogenic for rabbits and not for rats and *vice versa*. This suggests the possibility that it may at times be pathogenic for man when rats are not affected. The bacilli are much fewer in number in septic cases than in the other forms of the disease. Dr. A. O. J. Kelly reported a case of papillomatous epithelioma of the pelvis of the kidney. The tumor was removed from the kidney of a patient sixty-one years of age. It was the size of a walnut and projected partly into the parenchyma of the organ. Interstitial nephritis of high grade was present, and the symptoms somewhat resembled those of renal calculus. Dr. Simon Flexner reported the results of investigations concerning the nature of the new tissue in cirrhosis of the liver and its distribution. The experiments were made possible by the recent discovery of a specific method of staining elastica. The results show that the new tissue is not elastica alone, as was at one time supposed. After staining this tissue, it and the cells were digested away by pancreatin and new tissue was still left. Further tests show that the new tissue is made up of all the kinds of connective tissue normally present in the liver. No one kind alone is increased in cirrhosis, but all kinds are increased. When the process is confined to the periphery the fibrous and elastic tissues are increased in amount, the elastica being derived from the adventitia of the blood-vessels and the fibrous tissue from that surrounding the bile-ducts. When the lobules are coarsely invaded, white fibrous tissue grows in from the periphery. The finer involvement of the interior comes from the reticulum which increases in amount.

County Medical Society.—At the stated meeting May 23rd, Dr. H. W. Cattell gave a kromoscopic exhibition of pathologic specimens by means of lantern-slides. The natural colors of the specimens were exceedingly well shown. The photographs shown had been taken through all the color-screens at once. This method is advised for the use of teachers of anatomy or pathology, as the kromoscope itself can hardly be used by a large class of students. It is also of value in the illustration of books, as a picture can be taken directly from the fresh specimen and the printer given the kromoscope, with instructions to reproduce the colors. Dr. J. P. C. Griffith read a paper upon laboratory feeding of infants in health and disease. Fat is the most variable ingredient in herd milk, but the centrifuge determines the amount where laboratories are not convenient. Physicians must not think that laboratory milk is an entity. Anything wanted can be ordered, the same as at a drug store. The objection has been raised that laboratory cream is a separated product. This is a trivial objection as practically all cream is so obtained these days. However, the cream will be skimmed at the laboratory if so ordered. Dr. Griffith begins with a low mixture, say .50 per cent. proteid, 2 per cent. fat, and 5 per cent. sugar. This formula is increased as the infant needs, not according to its age but according to its gain in weight. Great stress is laid on weighing the infant once or, better, twice a week. A case was cited in which the proteids were increased because of the age of the child, although it was doing well. It at once lost weight but began gaining when the proteids were decreased. The fact was emphasized that very small changes in the formula will be noticed in the child's condition. This argues for percentage formulæ. Three cases were detailed where laboratory milk had been used but in wrong proportions, each case showing marked improvement when experimentation determined the proper percentage. These cases might have been used as an argument against laboratory milk when they were really due to carelessness on the part of the physicians. Dr. L. S. Somers stated his results from the internal use of adrenal extract in 21 cases of hay-fever. Tablets were found to be preferable to a solution, one five-grain tablet being given every two or four hours as the patient could stand. As high as seventy-five grains daily were given in one case with no untoward effect and with no effect upon the disease. In 6 cases the paroxysms of asthma were more frequent during the use of the extract. In 5 others asthma first appeared during its use. The conclusions reached are that adrenal extract is practically inert in its action on hay-fever when given internally. Some effect is obtained when the tablets are dissolved in the mouth. It is of service when applied locally to the mucous membrane of the respiratory tract.

CHICAGO.

Down-Town Emergency Hospital.—Dr. Ger-

trude Wellington recently appeared before the Finance Committee of the City Council and urged the establishment of an emergency hospital in the down-town district. The Finance Committee expressed their willingness to recommend the appropriation of $2000 to aid in the undertaking, with a share in $3,000 now given annually to St. Luke's and Mercy Hospitals.

To Treat Consumptives.—Health Commissioner Reynolds says that Chicago has already taken steps toward preventing the spread of this disease, and in commenting on the report from Boston that the health authorities there had determined to disinfect every house containing a consumptive patient and to begin a campaign against the contagion, he is quoted as saying: "It is a mistake to try and make a consumptive feel that he must be an exile or a leper to be shunned by everybody. In the first place, the disease may drag along for forty years without any sudden developments to enable a doctor to diagnose it correctly, and then again it is curable. The best way is to get the patient to believe that he can be cured, and that he can also be of use to the community by preventing the spread of the disease. If consumptives would deposit their sputa in a paper and then burn the paper, there would be no fear of contagion.

Formaldehyde and Milk.—In the office of the milk-inspector are samples enough of adulterated milk to show that the use of formalin is widespread. The milk-inspector has received letters from several milkmen which in substance state that the prompt prosecution of dishonest dealers would protect the honest milk-deliverers quite as much as it would the customers. The Health Department has decided to use moral suasion for a time, then, if such measures are not effective, the milkmen who use formalin as a preservative will be prosecuted. A number of notices have been sent out and the milkmen are stopping the use of the chemical almost everywhere. It is believed that a great deal of the damage done by this preservative has been wholly unintentional; that many of the milkmen have used preservatives with honest purposes and no thought of danger. The stand taken by the Health Department against the use of formaldehyde will go a long way toward stopping the practice of poisoning the milk intended for the nourishment of little children and sick persons, but prompt action by housewives and mothers in ceasing to deal with all milkmen whose milk stands the test of time for too long a period would settle the whole difficulty.

Disinfection of Chinatown.—The Health Department inspectors of sanitary conditions are making a round of the Chinese quarter in an attempt to improve conditions in that district of the city. The recent developments as regards bubonic plague have led the Department to increased vigor in insisting upon better sanitary conditions. The inspectors will disinfect by wholesale the Chinese district, and two inspectors have been instructed to watch the Chinese habitations for the arrival of newcomers from any other city on account of the possible transmission of bubonic plague. A mandate has been issued that cleanliness must be observed whether the occupants of dwellings enjoy the process of disinfection or not.

Prosecution of Dowieites.—The attorney for the State Board of Health, it is said, has obtained evidence on which he expects to direct civil proceedings against certain of Dowie's followers, and probably Dowie himself. The proceedings will be in the form of a suit for damages claimed by a Mrs. Bone for injury to her daughter's health. The disclosures made concerning the girl's treatment show that the institution of Dowie is beyond toleration by the Health authorities. The evidence to be brought in the courts will show the necessity of revising the provisions of the Medical Practice Act which permits these faith healers to operate.

Bubonic Plague.—In the weekly bulletin of the Health Department, Dr. Arthur R. Reynolds takes occasion to say that recent developments in the plague situation fully warrant his action taken more than four months ago, when he urged the Surgeon-General of the United States Marine Hospital Service to call a conference of public health officials for the purpose of deciding upon uniform and cooperative measure for preventing the introduction and spread of bubonic plague in this country. For want of such measures the State of Texas has now quarantined against the city of San Francisco, and a large area of the country is in a state of alarm bordering on the panic which so often breeds shotgun quarantines in the yellow-fever zone of the South. It is to be feared that this is but the beginning of costly and vexatious interruptions of travel and traffic wholly unwarranted by any actual menace to the public health of the country. In the absence of authentic information, frankly published without suppression or concealment, disquieting rumors will gain currency; restrictive efforts will lack uniformity, and the efficiency to be gained by cooperation; business interests will be injured and the public mind will be so perturbed that the public health will suffer far beyond any probable results of the plague itself. What now remains for Chicago, as for every other community, is to set its own house in order; to spare no effort for that degree of civic cleanliness which, while making the spread of the bubonic plague impossible, will also improve the general health. More has been done in this direction during the past few months than in any spring period for many years, and Chicago is to be congratulated on the success of the efforts of individual citizens and householders for a cleaner city. The change wrought in the appearance of many alleys is a revelation. It is an object lesson which is being copied widely and gives promise of the complete abolition of the disease-breeding manure box and

the equally obnoxious garbage box, illegal nuisances that are the cause of more avoidable disease and death than any other. When they are finally abolished, Chicago will have no reason to fear the plague or any other pestilence.

Vital Statistics.—For the first time in many weeks no death from influenza was reported last week nor was it mentioned as a complicating cause of any other disease. One death from smallpox, seven from measles, and six from whooping-cough were reported. There were 45 deaths from violence and suicide. There were 502 deaths reported last week, this being 25 less than the preceding week, but 106 in excess of the corresponding period of last year. A very unusual feature of the week's mortality-list for this time of the year was the report of three deaths from sunstroke. The very hot weather of the early part of the week was responsible for the acute intestinal diseases, there being 36 from this cause, as compared with 17 the week preceding.

Inspection of Milk.—At a meeting of the Chicago Medical Society, held May 23d, Dr. Arthur R. Reynolds spoke on this subject. In referring to the results of milk-inspection by the city, he said that when the inspection of milk was begun by the city it was found that 45 per cent. of the milk sold in the city was below the standard. Now only 10 per cent. is below the required grade. The great trouble with the system is that it does not prevent the adulteration of milk by second- and third-hand dealers. The people must be instructed as to the quality of milk and must remember that they cannot hope to buy good milk for a small price.

Inspection of Herds by Veterinarians.—Dr. A. H. Baker discussed this subject. It is now a well-accepted fact that dairy-cows must be examined by competent State veterinarians at least once a year. No animal is more susceptible to disease than the average dairy-cow. Every little indisposition of the cow, and, indeed, every different mental state, has its effect on the milk. A change of diet will have its immediate effect. The only way to obtain a good milk-supply is to have healthy cows. The only way to be assured of the health of a cow is by the annual tuberculin tests of veterinarians. The tuberculin test will show immediately whether or not the cow tested is diseased, and the best proof of its reliability is found in the fact that only 2 per cent. of the cows killed were found to be without disease. There is no doubt about the advisability of having the State conduct these annual tests of the dairy-cows.

Feeding of Milk to Infants.—Dr. W. S. Christopher discussed this phase of the subject, and declared that there are children whose constitutions are such that milk has the effect of a poison on them. He advocated feeding fresh beef-juice to children who are thus constituted.

The Dairy Farm.—Mr. H. B. Gurler dwelt upon this topic. He described the precautions that should be taken in producing the marketing milk. He believes that absolutely pure milk could be kept on ice for two weeks and still be fresh and sweet.

GENERAL.

Astor's Gift to a Hospital.—William Waldorf Astor has sent a check for £10,000 to the Maidenhead Cottage Hospital in celebration of the coming of age of his eldest son.

Couldn't Afford to Lose Him.—A Scott County (Kan.) physician recently moved to another part of the State because he could not make both ends meet in his practice. But his old patients needed his services so badly that they circulated a petition asking the County Commissioners to appropriate a bonus of $500 annually to the doctor on condition that he should return. The Commissioners made the appropriation, and the doctor returned.

Infection from Sweatshops.—The Mothers' Congress at Des Moines, Iowa, May 25th, listened to a paper on the sweatshop, read by Mrs. Florence Kelly of New York, Secretary of the Consumers' League. It seems that it is the fault of women that sweatshops exist, because if garments made under sanitary conditions by fairly paid labor were insisted upon, the dealers would furnish them. The Consumers' League has, after years of labor, made a list of fifteen factories where women's underwear is manufactured under proper conditions, and the goods made by these factories bear the label of the League. Mrs. Kelly considers that the danger from germs is as great in sweatshop garments as in children's food.

State Colony of Insane.—There has been reported to the Massachusetts Assembly a bill for the State support of the insane paupers in the State. The bill goes into effect on January 1, 1904, and it forbids any city or town to have any asylum for the insane after that date, or to be liable for the board, care, or treatment of any insane person. The bill provides for the purchase of from 1500 to 2500 acres in some tract, at a cost of not over $25,000, and the expenditure of not over $50,000 is permitted for the erection of buildings for the dwellings of the insane. Thus there will be a State colony of the insane, living in small numbers in separate cottages. It is expected that the able-bodied insane will be set to work on land.

Increasing Population of Japan.—A correspondent in the *Evening Post* writes: "On witnessing the high state of cultivation to which the fields are already subjected, and the extent to which the arable land is already occupied, one soon becomes oppressed with the problem of what is to become of the increasing population after a few years. Everywhere one sees swarms of children, and, on consulting statistics, it appears that the present rate of increase is about 500,000 annually, or a little more than one per cent. Ten years ago the population was about 37,000,000. At the present time, including the 3,000,000 annexed in

Formosa, there are 46,000,000. An important factor in the future increase is to be found in the decreasing death-rate resulting from improved sanitation and the dissemination of higher medical skill. Taking all these things into consideration, it is not too much to expect that, with a continuance of present social conditions, the population of the Empire will double within the next fifty years, reaching 100,000,000 shortly after the beginning of the second half of the century."

Smallpox in Excursion Party.—The steamer "New England," of the Dominion Line, sailed from Boston February 1st with a party of excursionists on a tour of the Mediterranean Sea. Upon arriving at Naples it was discovered that smallpox had developed among the members of the crew and had been communicated to some of the passengers. The state of affairs was not known to the passengers generally, and while the excursionists were visiting Rome, the captain of the ship discharged the passengers' baggage and after disinfecting his ship sailed suddenly for Liverpool. The baggage was finally fumigated and forwarded overland to Liverpool. Transportation for the passengers was also secured. One of the excursionists, a young lady from Minnesota, died at Rome from the effects of the epidemic; and another excursionist, a lady from Worcester, Mass., also died from pneumonia.

A Doctor Recovers Damages.—Dr. Walter B. Wellbrock, of Brooklyn, secured a verdict recently in the Kings County Supreme Court for $25,000 for damages received by the running down of a tally-ho coach by a train of the Long Island Railroad. Dr. Wellbrock's injuries were most severe; his right arm was fractured in three places, his left leg in four places, and his left arm in two places. His left arm was dislocated at the shoulder and his left patella was fractured. Many others on the coach were also injured but not so severely.

A Professional Promoter of Charitable Enterprises.—One J. W. Stokes, a young man of charming address and kindly demeanor, seems to have conducted in Boston, St. Louis, Cincinnati, Cleveland and many other cities, a number of enterprises calculated to raise money for charitable causes. He seems to have found this work rather more remunerative for himself than for the institutions concerned. For instance, Mr. Stokes has lately consummated an entertainment for the benefit of the Sunshine Mission, whose purpose is to improve the condition of the youth of the "Hell's Kitchen" district in this city. The mission benefited to the extent of $55.00. The rest of the money received—a very goodly sum—was appropriated by Mr. Stokes in payment for his own services. It appears to us that a good many enterprises which have of late years been conducted ostensibly in behalf of hospitals and dispensaries in this city, have been managed upon Mr. Stokes' plan.

Obituary.—Dr. Charles M. Newell, physician, sailor, poet and writer, died at his home in Watertown, Mass., on May 25th. When fourteen years old he ran away and shipped on a whaling craft. He became a captain and spent a winter in the Arctic regions, exploring to a point farther north than any American up to that time. He spent some time in the Hawaiian Islands and was decorated by King Kalakaua in 1888. He practised medicine for thirty-five years in and near Boston.

Army "Contract Surgeons."—A bill for the relief of the acting assistant surgeons of the Army has been introduced in the United States Senate and is now before the Committee on Military Affairs. It ought to become a law. These surgeons, called also "contract surgeons," were employed during the Spanish War and many of them are still in service in the Philippines and in this country. Their monthly salary is $150; they wear army uniform without any badge or indication of rank, and they perform all the duties that regular surgeons perform at larger salaries. This bill, if passed, will remedy a great deal of injustice. It provides that hereafter all contract surgeons shall have the allowances and privileges of first lieutenants, except the pay, which shall continue to be $150 a month. All acting assistant surgeons appointed since May 1, 1898, shall be paid for sick leave and for ordinary leave not to exceed thirty days in each year of service; and gives them the right to file claims for back pay for such periods of leave, for commutation of quarters, and for travel pay and allowances, "which may have been withheld from or not paid to them." Other sections of this bill are also commendable. The medical service, both in the Army and the Navy, is not especially attractive to good men; and any movement tending to make it more so should be furthered.

The Plague.—There have been no new cases discovered in San Francisco since our last report, although a suspicious case is now under investigation. In all nine cases had occurred prior to May 15. The Board of Health has placed all of Chinatown in quarantine and no one is allowed to enter or go out of the barriers. In the mean time a renewed house to house inspection is being made and sanitary measures enforced. The special correspondent sent out by the *New York Herald* is presenting to the public in a forcible way the reports already communicated to the proper authorities of the Board of Health and the Marine Hospital service and is thus establishing the confidence of the public in the authorities. In the mean time the larger cities of the country which are possessed of quarters known as Chinatown are anticipating any future trouble by inspecting and enforcing sanitation. At Rio Janeiro, May 27, two cases were reported in Hospital Misercordia, one in the Hospital Carmen, one in the barracks of the First regiment of infantry, and other cases throughout the town. On the same date at Port Said one new case of plague

and one new death, both the victims being Arabs, were reported. There are now eleven Arabs in hospital, and four Europeans. The total number of cases to date is forty-four, of which twenty-one have ended fatally and eight have been cured.

In India according to a special to the *New York Times*, April 26, the outlook is of the gloomiest possible description. From every stricken province the weekly returns show steady increases in the totals of people on famine relief, with the solitary exception of the Punjab, where the figures are for the time being more or less stationary. There are now close on 5,500,000 persons in India in receipt of famine relief, while the actual number of people who are severely affected by the extreme scarcity must by now be close to 100,000,000.

The spread of the plague throughout India is such as to give rise to the most serious alarm. For the last three years or so the plague has to a large extent been confined to the west side of India, especially Bombay. But it has gradually spread over a vast extent of country, and at the present moment there are few provinces which are not to some extent afflicted. In Bombay, Sind, and Southern India it is rampant. There are many deaths daily in Calcutta and its neighborhood. Throughout the lower provinces of Bengal there is great mortality from this cause. Recently there have been cases in the northwest provinces. Certain districts of the Punjab are afflicted. And there are signs that the fell disease will gradually extend all over the country.

There are many disquieting features about the course of the plague. To prevent its spread it is absolutely necessary to carry out measures of disinfection and isolation. These the people resent to an extraordinary degree. They are convinced that the Government doctors have orders to poison off all patients, and thus to stifle the spread of the disease. They proclaim that no one who goes to a Government plague hospital ever comes out of it alive. The result of all this agitation is that there have been serious riots and disturbances arising from plague prevention measures.

The doctors employed on plague duty go about in fear of their lives, for it is only necessary to be known as a plague doctor to cause a mob to assemble for the purpose of murder. Some soldiers driving through a native town a few days since in a perfectly quiet and harmless manner were mistaken for plague doctors. They were immediately set upon and so beaten and ill-treated as to be left for dead.

Smallpox in the Philippines.—Surgeon-General Sternberg describes the situation in the Philippines as regards smallpox and vaccination as follows:

"At the time of the occupation of Manila smallpox prevailed as an epidemic in the city and the neighboring towns and villages, particularly among the native population. The troops were exposed to the infection within a day or two after their arrival. The period of incubation is two weeks, and on September 3 the first case was taken from the command and isolated in a smallpox ward established as a part of the First Reserve Hospital. Arrangements were made and promptly carried into effect for the protection of the troops by vaccination, but cases of the disease occurred until March 31, 1899, when all danger of its epidemic spread was declared by the Chief Surgeon to be at an end. During this time 236 cases were reported, with seventy-seven deaths. During the remaining nine months of the year 1899, twenty-three deaths were reported, making a total of 100 in the eighteen months. The unusual length of time occupied in controlling the disease was due to the difficulty of obtaining fresh vaccine. That which was sent from this country evidently suffered deterioration during the long voyage. Ultimately fresh virus was obtained by cultivation in the laboratory of the Board of Health of Manila. As compared with our losses from this disease in the Philippines it may be stated that the German army, in which vaccination is carefully conducted, lost 278 men by death from smallpox during the seven months of the Franco-Prussian war, while the French army, during the same period, had the appalling loss of 23,000 men from this disease. Our white troops during the civil war reported 4717 deaths deaths from smallpox."

CORRESPONDENCE.

THE PATHOLOGICAL INSTITUTE AND THE STATE COMMISSION IN LUNACY.

To the Editor of the MEDICAL NEWS:

DEAR SIR:—A well-established principle of the State Commission in Lunacy is to take no public notice of inuendo, contumely and carping criticism, which may be anticipated by a State department with interests as great and varied as those of the department of insanity in New York. Your recent editorials—the last appearing in the issue of the MEDICAL NEWS of May 19th, *instant*, which bears the guarantee of a responsible and influential journal, although the ear-marks of an individual—contain so many perversions of fact and libellous intimations, that they form a sufficient reason for this departure from precedent, especially on the part of the writer. He can better reply to these misleading statements, which he ascribes rather to misinformation than to any intent to do an injustice, by supplying correct data in a brief résumé of the circumstances and motive which led to, and the needs to be served by, the creation of a central laboratory (the Pathological Institute) for the State Hospitals, as well as the present effort of the Commission to have its work modified in the degree necessary to meet existing hospital requirements. When the Institute was organized in 1896, there were nine (9) State Hospitals, but by the transfer of the New York City and Long Island institutions to the State,

the several units of organization now number fifteen (15), with an aggregate insane population of 22,000, receiving approximately 4000 patients annually, and having about 130 physicians engaged in the medical service, exclusive of the Institute staff. The fundamental element of the "State Care Act" was cooperation. This applied chiefly to administrative requirements, both in the interest of improved service and for economic reasons, and soon became an established function. Later, cooperation seemed equally applicable to scientific research. Hitherto each hospital had a laboratory, usually with inadequate equipment, and the superintendents agreed that if the several hospitals were united in a central laboratory, with a directing pathologist of a higher grade than it was possible for any individual hospital to afford, it would result in an improved service and economy, and would enhance scientific research. It was always maintained that the central laboratory should be created "primarily for the State Hospitals," as the published reports of the Commission and of the several hospitals will show. Clinical and pathological research were to be prosecuted with a mutual interest. The central laboratory, which was created in 1896 and entitled "Pathological Institute of the State Hospitals," was to be virtually the several smaller laboratories united into one, giving thereby the advantages which usually accrue to concentrated effort and united endeavor. But the union of clinical and pathological work was not to be disturbed, and their codependence was rather to be cemented than disrupted. The Institute after all was but a State Hospital laboratory of large proportions, located in New York City because it was in close proximity with two-thirds of the committed insane in the State. When, therefore, the Director of the hospitals' laboratory began the process of amputating the hospitals from it—severing their relations—and manifesting an unmistakable tendency toward the creation of an independent institution, substantially averring in an official document that the hospitals were not required, that they had no suitable material in the line of research he contemplated, it became justly a cause for complaint by the medical superintendents, and the Commission was petitioned to save for the hospitals this important and necessary adjunct to their clinical work. With the complete and costly equipment of the central laboratory, the hospital laboratories were not maintained except to meet the ordinary clinical requirements, all special research being dependent upon the cooperative laboratory. It appears astounding to the well-informed and shows an ignorance of insane hospital possibilities to claim that no value for pathological purposes attaches to the enormous number of cases received in them; many of the admissions being of the same types received in general hospitals, such as delirium, toxic cases, etc., which go to make up the cases "not insane."

One of the chief benefits anticipated from centralization, and announced by the Commission upon the creation of the Institute, was "to provide instruction in brain pathology and allied subjects for the medical officers of the State Hospitals, and to other members of the medical profession," etc. This function has been in a great measure ignored, and in the few instances where medical officers were received at the Institute, it was a matter for complaint by the Director that it retarded research by absorbing the time of the staff to such a degree as to be discouraged, and experience indicates that it has been.

At the bi-monthly conference of hospital superintendents, held in Albany in January, *ultimo*, there was a unanimous expression of opinion and sentiment, which was emphatically favorable to a continuance of the Institute and original research, but in an equal measure called for a modification of the existing scope and methods of its practice, to meet the practical and clinical needs of the Hospitals. The following excerpts are from the stenographer's notes: "The lines on which it has been conducted have not been for the best interests of the Hospitals, and for the interests of the insane in them." "The foregoing expresses very clearly my ideas in regard to the Institute. . . . I believe the work could be changed—could be more practical." "We have not been closely enough in touch with it . . . bring the hospital work closer to research." "I think the work should be more closely identified with the Hospitals." "Research could have practical application in a measure, at least, for the benefit of the insane in the Hospitals." "I want to see it (the Institute) preserved, but its work should more nearly meet the needs of the Hospitals." "I think the work has departed from the original design and does not agree in fact with the scope outlined by the Director in his introductory," etc., etc. These opinions could be multiplied, and although unanimous with the New York State hospital superintendents, it is the prevailing sentiment of psychiatrists engaged in hospital work and cognizant of hospital needs.

It is sincerely to be regretted—and by none more than the writer—that personalities should enter into a controversy of so grave a nature as this. The largest measure of spleen and complaint seems to be opened upon the medical member of the State Commission in Lunacy, and chiefly, it is assumed, for his former loyalty to the Institute as administered and for his support of the Director. The writer appealed to the superintendents to withhold criticism and complaint, relying upon the assurances of the Director, frequently repeated, that a demonstration would soon be made which would receive the plaudits of the scientific world and would quiet all critical and complaining elements. The waiting process is still going on, for there has been no disturbance of the Institute, either in its organization or methods. Thus far the demonstration is confined to the promulgation of a theory not generally accepted. It is not denied that the Institute has effected some excellent work in

original research and has still more in progress.

Inquiry into economic features of the work has been forced upon the Commission. The annual expenses of the Institute has been approximately $40,000. The specific appropriation for 1899 was $36,000. The rental for rooms is more than $6000 per annum. Criticisms were frequent from medical men and neurologists of New York and elsewhere, physicians who have recently signed a protest against disturbing the present methods of the Institute, complaining of illegitimate application of public funds to the self-aggrandizement of the Director and his associates, in promulgating impossible and unscientific theories. It was charged that under the influence of a psychologist (not a physician) the Director was making the so-called scientific work of the State Hospital system the gibe of psychiatrists and pathologists. Through it all he was faithfully supported by the Commission, the President appearing annually before the respective appropriation committees of the Legislature, and upon his responsibility as a public official stating that the public moneys to be expended by the Institute were requisite, that no economies were possible, and that it was being conducted in accord with the avowed purposes of its creation.

It was not until the autumn of 1899, and after the Institute had been practically vacated for more than three months without the approval of the Commission (although the contention of the Director had been that a light, airy and cool location was necessary, regardless of cost, on account of the necessity of continuing work during the hot weather), that in response to a sharp and peremptory official criticism of such action, aimed particularly at the medical commissioner, an inquiry was made into the scope, methods and administration of the Institute. Up to this time, the acts of the Director, as well as his organization and methods had been loyally supported by the President of the Commission. Besides the Director's associates respectively in charge of the departments of pathology, normal histology, pathological histology, cellular biology, bacteriology, physiological chemistry, psychology, anthropology, and comparative neurology, there was also a corps of lay employees, known respectively as librarian, archivist, preparator, indexer, accountant, stenographer, janitor, janitress, several of whom had assistants. As soon as this officer, however, proposed an inquiry, editors of newspapers (medical and lay), State officers, and especially the Governor, physicians, and especially neurologists—who had previously been ignored and condemned as critics or colleagues and scouted as peers—were appealed to for support on the ground of an attack aimed particularly against scientific research. This contention is unfair, baseless and without a scrap of evidence. It is ethically audacious and extravagant, unjust, in the face of evidence showing the chief object of the inquiry to be the enhancement of scientific research in the pathology of insanity, aided by clinical resources.

The Commission called to its aid a committee of three physicians who are preeminent in their departments of practice, two of whom were psychiatrists and one a teacher of pathology in a leading university, to examine the scope and methods of the Institute, and report as to their value, the justification of the department of insanity in maintaining so comprehensive a scheme of research and the degree in which the present development of the Institute realizes the purposes of its creation. The report is too lengthy to quote in this letter, but the conclusions are as follows:

"1. The Pathological Institute should be maintained, but reorganized on a basis that shall have systematic teaching as its main function.

"2. It should teach the fundamental principles whose study and application must lead to the clinical, anatomical and chemical research necessary for advancement in the curative and preventive treatment of insanity.

"3. It should have as its director a physician who has had training in clinical psychiatry, besides being a competent pathologist.

"4. It should be located on property of the State, in a building of its own, as near to the metropolitan medical schools as is practicable.

"5. As an essential of its teaching function its building should adjoin, or be a part of a small hospital for the insane for the reception of acute cases and others appropriate for investigation.

"6. Entrance into the medical service of the State Hospitals should be conditioned upon previous training in the Pathological Institute."

In contrast to the foregoing facts, and impartial statement of the attitude of the Commission, its President, and others, I hope your readers will refer to the editorials in the MEDICAL NEWS *in re* the Pathological Institute, and the following petition which has been assiduously circulated for signatures, with an accompanying letter. I trust you may see fit to publish this petition and letter *verbatim et literatum*, as follows:

"In view of the fact that the Pathological Institute of the New York State Hospitals, founded by Dr. Carlos McDonald" (The official records show that the Institute was created by law, under the direction of *the* State Commission in Lunacy which was composed of three commissioners.—Note by the writer) "in the year 1896, has been carrying on scientific research in Psychiatry on lines of investigation as worked out by Ira Van Gieson, the Director of the Pathological Institute and his associates, thus helping to further the advance of Psychiatry; and in view of the fact that Dr. P. M. Wise, President of the State Commission in Lunacy of the New York State Hospitals, and Dr. Edward Cowles, Superintendent of the McLean Asylum, Chairman of the Committee appointed by the above-named Commission in Lunacy (*sic*), to sit in judgment and pass sentence on the work and principles of the Pathological Institute have decided and have actually attempted under the plea of paternal guidance and legislative supply of resources, to interfere,

subvert and destroy the scientific work of the Pathological Institute, handing it over to the 'superintendency of New York State Asylum superintendents,' and putting psychiatric investigation under 'their direction and control,' according to the old asylum methods, to do as Dr. Wise insists what the laboratories have always done in the State Hospitals, "resolved, that we, the undersigned, protest most emphatically against such a ruthless act of subverting and destroying a scientific Institute of great promise for the science of psychiatry, and condemn the interference with the scientific research work of the Pathological Institute, and protest against the crippling of its methods and principles of scientific investigation, either by forcing it to labor in the old pathways of asylum routine or to become the 'handmaid' as the committee puts it, of asylum men working at the will and command of asylum superintendents, or to divert its energies into educational schemes; and that we sustain the Pathological Institute along its present lines of organization, and principles and research.

"E. L. Trudeau, M.D.,
Edward D. Fisher, M.D.,
Graeme M. Hommond, M.D.,
E. C. Spitzka,
J. George Adami, M.C., M.D., R.S.E."

The following letter shows conclusively that duplicity is occasionally an implement of psychopathologists, and will explain to many signers of the "milder protest"—which the writer, by the way, read at the recent meeting of the American Medico-Psychiological Association, with the alleged signers—and that even apostles of higher research may fear "inexpedient truth." It may also explain the perversion of fact so freely promulgated of late, regarding the attitude of the writer. It would seem that not much "mature deliberation" was required to establish the value of either document.

"Pathological Institute,
New York, May 17, 1900.

"Dear Doctor:—

"Will you please look over the accompanying protest against the crippling and destruction of the work of this Institute, and let me know if you feel like joining with several men in New York, Boston, Philadelphia and Baltimore with your signature. I am in great haste to get the returns in order to present the protest at the coming meeting of the American Medico-Psychological Association. For I apprehend at this meeting that an issue will arise determining the fate of our cause. I have only had a few hours this morning to collect such New York signatures as you see appended. I enclose a much stronger protest, but which upon more mature deliberation we thought was too inexpediently truthful, and we shall therefore not use it. I wish very much to get the returns on Monday morning. If you think that answer by return mail would be too late to reach us, please telegraph us collect. *As far as we are concerned* we should like to have signatures to the *forcible protest*, although we should not present this at the American Medico-Psychological Association, because the milder draft would be more effective there.

Yours very truly,
Ira Van Gieson."

It probably will not require further examples of the effort to "mold professional sentiment" than is illustrated above. When it is stated that the Commission has respectfully invited the Director to cooperate with it, and to submit suggestions applicable to bringing the Institute within statutory requirements, without even the courtesy of an acknowledgment, the imagination of the reader can complete this history.

It may be stated that there has been no suggestion or proposition emanating from the Commission or any Commissioner, or from any superintendent of a State Hospital, to "interfere, subvert or destroy the scientific work of the Pathological Institute," or even to disturb it. All such accusations are the product of a morbid fancy, and might be explained as arising from a symptom group, which forms a common enough clinical picture. There has been no attempt at persecution; on the other hand the utmost graciousness has been extended, and forbearance has been shown beyond any official precedent, in view of the duties and powers of the Commission, in Chapter 545, of the Laws of 1896, which is as follows: "The Commission shall appoint a director of the Pathological Institute, who shall perform, under the direction of the Commission, such duties relating to pathological research as may be required for all of the State Hospitals for the insane."

Finally, the Commission, the superintendents of State Hospitals, all true friends of progressive science, as well as the Medical News, desire a continuance of pathological research into the causes and pathology of insanity and the continuance of the Institute without abatement, but to be administered in compliance with the requirements of law, without extravagance, and in accord with the consensus of professional opinion and the dictates of scientific common sense. This cannot be better illustrated as regards practical psychiatrists than to put in evidence the following unanimous request of the superintendents of the New York State Hospitals:

"In view of the recent discussions as to the work of the Pathological Institute of the New York State Hospitals, the undersigned superintendents of the hospitals request the Commission in Lunacy to make such modifications of the work as will bring about a closer relationship between the clinical and pathological departments, while affording at the same time the widest scope to original research work. We desire the encouragement and advancement of such original work, and believe that the importance of clinical investigation should receive recognition, having in view the welfare of the insane and the advancement of science.

(Representing hospitals with an aggregate of 22,000 patients.)

It is therefore to be regretted that you have been so far misled as to state, editorially, that "attacks *in* (?) scientific research are committed by a man who, if he is not, still claims to be the chief and leader of the psychiatric profession in the United States." (The writer has not the egotism to apply this title to himself; but who is he?); and that "a heavy iron hand is put on its" (psychiatric research) "very heartstrings with the intent to crush out its activity and life." Moreover, it is hoped that you will correct, as far as possible, this injustice toward an earnest, honest and law-abiding impulse to uplift science and enhance research without violating the statutes of the commonwealth.

OUR LONDON LETTER.

[From Our Special Correspondent.]

LONDON, May 24, 1900.

THE ANTIVIVISECTION CAMPAIGN—ACTION AGAINST THE BRITISH MEDICAL ASSOCIATION—THE POLYCLINIC—EXOPHTHALMIC GOITER WITH UNILATERAL PROPTOSIS—THE SOUTH AFRICAN WAR—BOER RATIONS—DO THE BOERS INTENTIONALLY FIRE ON HOSPITALS?—DIFFICULTY OF DISTINGUISHING THE RED CROSS FLAGS—NECESSITY FOR MORE OBVIOUS ARRANGEMENTS—THE PREVENTION OF LEAD-POISONING AMONG POTTERS—OUTBREAK OF LEAD-POISONING AMONG SHOEMAKERS—PROFESSOR VICTOR HORSLEY'S ATTACK ON MODERATE DRINKING.

THE action brought by Mr. Charles Adams, one of the leaders of the antivivisection campaign and editor of the *Vernlam Review*, against the British Medical Association shows the straits to which the antivivisectionists are reduced for want of arguments. It seems that Mr. Adams, having read the Home Secretary's statement in Parliament that no experiments were performed on cats or dogs without anesthetics, addressed a letter to him as to 190 experiments returned in the inspectors' reports as having been performed under certificates permitting experiments without anesthetics. The Home Secretary replied that Mr. Adams was in error in thinking that the experiments were performed without anesthetics. Mr. Adams, having then an apparent contradiction, wrote to the gentlemen who carried on the experiments asking them to explain. He charged them with having performed experiments under anesthetics while they had obtained certificates on the express ground that the experiments could only be performed without anesthetics. He added that the statement of the Home Secretary appeared to cast a serious slur either upon their good faith or their professional competence, and that silence would be taken as assent. The judge said of this effusion: "A more impertinent letter was never written from one man to another." The *British Medical Journal* characterized the letter as inaccurate, misleading, and threatening, for the certificate referred to provided that the animal should be under an anesthetic "during the whole of the initial operation." "The irresponsible editor" of the *Vernlam Review* was said to be either ignorant of the terms of the license or too careless to ascertain them while impugning the good faith of those who advanced the healing art by experimental methods. Hence the action which resulted in a verdict for the defendants—the only possible one.

At the Polyclinic Dr. Ord showed a very rare case of exophthalmic goiter in which the proptosis was unilateral. The patient was a woman who said that enlargement of the thyroid gland began after marriage. The projection was greater on the right than on the left side and the ordinary symptoms, tremor, palpitation and rapid pulse, were present. There was marked proptosis of the right eye, none of the left. Although Dr. Ord has seen a great deal of the disease he never previously has observed a case with unilateral proptosis.

The South African war is still the dominant topic in professional as well as lay circles. According to a daily paper the details of the Boer commissariat are as follows: The ordinary rations consist of a pound and a half of fresh meat daily, a pound and a half of coffee, three pounds of sugar and five pounds of flour weekly. Statements of savage disregard for the rules of the Geneva Convention by the Boers constantly appear in the press, and are accepted by most people. It seems to be forgotten that only one side of the question is heard and that with very few exceptions the attitude of the newspapers is far from impartial. A charge of firing on hos-

pitals has often been made. A letter from Sir William Thomson, Surgeon-in-Chief of the Irish Hospital Field Force, which has just been published, throws a good deal of doubt on this assertion. Since he has been in the field he has come to understand how a hospital may be shelled by an enemy in ignorance of what it really is. The red cross flags not uncommonly lie motionless along the flagstaff in folds and can be identified only at short distances. Although he knew where to look for them, in calm weather they were indistinguishable at 200 yards. On the wagons the red cross is much too small. The enemy only sees groups of tents precisely like those used by the fighting men. He suggests that every marquee and bell-tent used for hospital purposes should have a very large red cross on the roof and sides, repeated on various aspects, and made as obvious as possible. In every case there ought to be a light canvas in a wire frame bearing a large red cross which could be hoisted when the flag is useless.

Professor Thorpe, Principal of the Government Laboratory, has delivered at the Royal Institution an important lecture on lead-poisoning. He pointed out that the evil is largely connected with the use of raw lead, white or red, employed as an ingredient of the glazing material, or in the composition of the pigments used in decorating ware. The comparative immunity on the Continent is largely dependent on the more general use of fritted lead. However, even with this form poisoning is not unknown. He has studied the conditions under which a frit yields its lead to dilute acids comparable to the gastric juice. It is mainly through the agency of the gastric juice that lead is toxic. He has found that the ease with which lead can be given up to solvents is largely dependent upon the ratio between the basic and acid constituents of the material. Provided that the sum of the basic oxides is not more than double that of the silica, the frit as regards lead has no greater solubility than about 2 per cent. He further discovered that by treating the frit in the process of grinding with weak hydrochloric acid practically all the lead which would otherwise be soluble could be removed, leaving the residue with substantially the same composition as before. Thus a frit containing upward of 53 per cent. of oxide of lead, giving 2 per cent. of soluble lead, has its solubility diminished to 0.4 per cent. These facts have induced the Home Secretary to call upon the manufacturers to discontinue the use of raw lead and to substitute for it fritted lead of a standard limit of solubility.

Lead-poisoning has occurred at Northampton from a somewhat unusual cause. It was noticed that a number of shoe-finishers came upon the union ill and that the doctor's certificates specified lead-poisoning as the cause. On investigation the evil was apparently traced to powders, known as Chinese red and yellow chrome, used in finishing the bottoms. On being applied to the soles of the boots the powders rise and are inhaled by the operatives.

Professor Victor Horsley has delivered at St. James' Hall a most uncompromising attack on moderate drinking, claiming that our present scientific knowledge is opposed to it. His experiments with Professor Krepelin's instrument showed that after a small dose of alcohol there was a slight shortening of the time of "simple reaction," as if the brain acted more quickly. But speedily slowing of the action of the brain began, which increased as long as the alcohol remained in the body. In the case of "complex reactions" (in which thinking was required) the action was never quickened; slowing began from the first. A further interesting fact had been demonstrated: After a small dose of alcohol Professor Krepelin's personal impression was that his brain worked more easily; but when he measured its actions by his instrument he found that the brain was working in an inferior manner. The influence of alcohol was therefore deceptive.

TRANSACTIONS OF FOREIGN SOCIETIES.

German.

TWENTY-NINTH CONGRESS OF THE ASSOCIATION OF GERMAN SURGEONS—THE OPERATIVE TREATMENT OF RENAL AND URETERAL CALCULI—PYELOTOMY VERSUS NEPHROTOMY — RADIOSCOPY AND EXPLORATORY INCISION IN DIAGNOSIS—DIAGNOSIS OF FUNCTIONAL ACTIVITY BEFORE OPERATION—SITE AND EFFECTS OF NEPHROTOMY INCISION UPON THE ORGAN—CASE OF CONGENITAL HYDRONEPHROSIS WITH DISPLACEMENT AND ITS TREATMENT.

Israel said that the difficulty and uncertainty of diagnosis and the dangers of the operative interference often hindered surgeons from proceeding. These factors should not be given undue weight because so many renal and ureteral conditions are amenable to surgical management and so closely simulate each other in their early stages as to make free exploration justifiable. In this manner are often discovered tubercular foci, small abscesses, incipient tumors, and various perinephritic processes. Even when visibly the kidney may appear normal, incision of it often gave good results and could be regarded as usually warrantable. Anuria due to the calculi constitutes the greatest indication for operation, no matter whether it depended on bilateral ureteral occlusion, or unilateral stoppage with reflex inhibition on the opposite side or with absence or deficiency of function due to previous or other disease of this (opposite) side. Spontaneous passage of the stone may be awaited as long as true renal colic persists, but in its absence the calculus must be promptly removed, because the patients become rapidly and severely uremic and the kidney degenerates so soon as to render its subsequent function doubtful if relief be delayed. The advent of symptoms of suppuration whether the stone be in the kidney, the pelvis or the course of the ureter, is another absolute necessity for

prompt action, because not only of the systemic effect of the infection, but also of its damage to the normal opposite kidney in the elimination of toxins. If the calculus be within the kidney-substance the divided organ should be temporarily drained. When the stone causes retention from time to time, endangering the organ by pressure, so soon as renal enlargement is made out, operate. Mere hemorrhages are the least indication for invasion of the organ for stone but are a sign for it in tubercular and other dangerous conditions. The dangers of the operation are slight in comparison with those of the condition left to its course, anuria, pyonephrosis, septic pyonephritis, etc. The mortality is only about 2-4 per cent.

The slow onset of signs of local infection, in order to protect the system and the kidneys from the danger of an extension of this process, is also a reason for treatment. Again, the depreciation of the patient from very frequently recurrent or chronic renal colic, with the possibility of sudden purulent invasion, also justifies operation. Finally, a stone in the ureter, with or without occlusion, palpable by the rectum, is a grave indication, because it always ends in a purulent condition. The danger of recurrence is not a contraindication, because dietetic and medicinal means may prevent it. A second operation for it is no more dangerous than the first. The passage of small non-faceted stones from time to time with intervals of perfect good health indicate internal medical treatment only.

Nephrotomy by its exposure of the entire anatomy is much more efficient than pylotomy for the removal of the stones, which may be so hidden as to escape detection through a small incision of the pelves. The small loss of secreting substance involved in the former may be neglected and suture of the renal parenchyma is simpler and surer than that of the pelvis. The technic is free shelling of the organ out of its fatty capsule, without damage to its capsule proper, down to the pedicle isolation of the ureter from the vessels; and temporary ligation of the vessels with a rubber-tube. The renal incision is lengthwise a little (2-3 mm.) toward the ventral aspect, thereby best avoiding the course of the vessels. Ureteral exploration with a sound is absolutely necessary.

Primary suture of the kidney is applicable to clean and occasionally to slightly infected cases when the urine is acid and the retention has been decreasing or is slight. Alkaline and purulent urine and marked or excessive retention, and a parenchyma studded with minute purulent foci demand free drainage. Such an organ sutured might go on to rapid general necrosis, and efficient drainage cannot be obtained through an opening in the renal pelvis. In grave cases of this condition it is best to divide the kidney into halves, sew each to a margin of the wound, drain freely, and give local treatment till the urine becomes nearly normal.

Primary nephrectomy for a first attack of calculi is not to be considered. It may be necessary for accidental otherwise irremediable injury to the pedicle, for persistent bleeding, as a secondary step, when reopening and tamponnade have failed. Tension on the capsule proper may here aid; hence the great motive for not damaging this when the organ is enucleated from its fatty bed.

Ureteral calculi can not be safely and positively diagnosed by sounds, as these may be arrested by other obstructions. The normal approach is after exposure of the kidney from above. Movable stones are coaxed into the renal pelvis, fixed stones are removed by longitudinal incision over them, closed by Lembert sutures which must be protected by a self-retaining catheter or drainage of the urine through the upper wound. Calculi in the cavity of the true pelvis can be reached by the vagina or abdominal wall from just above Poupart's ligament, with the great disadvantage of a small field for the later treatment of the ureter. Whether the ureteral occlusion should be at once removed depends on its accessibility and the general condition of the patient. Often it is best to fulfil only the vital indication, relieving the pressure on the organ and the onset of uremia. At a second sitting the ureter can be thoroughly investigated. Great care must be exercised not to be content with removing the first palpable and perhaps movable stone, because it may not be the true offender, whether we are dealing with the exposed ureter or seeking to determine which side in bilateral trouble was primarily affected. The decision on this last point is exceedingly difficult for occlusion occasionally begins without colic; the pain may be definitely referred to the opposite side; the thickness of the abdominal walls and the onset of tympanites may cloud the physical signs; a palpable tumor may be an old hydronephrosis without symptoms, whereas the invasion of the opposite side without a tumor may be the condition; focal tenderness and reflex muscular rigidity are the best single signs but fail often. The same uncertainties apply to cases of ureteral stone within reach from the vagina and rectum. Above all the operation must first expose the kidney, not the ureter alone for a stone in it, because only in this way can a destroyed or reflexly inhibited kidney, as well as occlusion of the channels, be fully known. If the wrong side has been approached, a day's delay before attacking the diseased side is necessary, unless uremia be present even in slight degree.

CZERNY (Heidelberg) said he has given up pyelotomy in favor of nephrotomy because the former leads to fistulæ too frequently. Twice he had found calculi at the distal end of the ureter, one came away spontaneously, the other required cystotomy. One of his patients died of uremia after removal of a stone from the left side. The autopsy showed occlusion and multiple calculi on the right.

KRÖNLEIN (Zurich) uses the radioscope and exploratory incision of the abdomen for diagnosis.

KOLACZEK (Breslau) reported a case of stone at the beginning of the ureter complicated by an extra-uterine pregnancy which was operated on at a second sitting.

ZONDECK (Berlin) pointed out that the renal substance should be cut ½-¾ cm. dorsally because the pelvis is behind the vessels and is, hence, more freely opened.

KUMMELL (Hamburg) read a paper on the diagnosis of the functional activity of the kidneys before operative interference. Catherization of the ureters has usually succeeded, without any instance of infection in his hands, but its significance is often difficult to determine. From one patient he obtained tuberculous urine from one and purulent from the other kidney. The former was removed and the latter finally recovered. The determination of the total urea is necessary. Alike from both and from each kidney individually. A comparison of the freezing points with those normal for the blood, the urine and the other body-fluids, often aids as variations in urea-excretion affect them to a marked extent.

BARTH (Danzig) reported a case of gangrene of the kidney and another of embolism of the lung in a paper on the diagnostic incision of the kidney. ISRAEL was of the opinion that gangrene usually is due to unduly firm suture of the capsule.

REISINGER (Mainz), speaking of the treatment of hydro-nephrosis, reported a case of congenital condition in which the kidney was situated at the promontory of the sacrum with its lower pole 3 cm. away from the bladder. After draining the collection of fluid away an anastomosis was made between the bladder and the thinned-out kidney by an inner continuous row of sutures, including the thickness of the kidney and bladder, and by an outer similar line taking in the peritoneum only. Complete recovery and good function of the kidney resulted.

SOCIETY PROCEEDINGS.

AMERICAN CLIMATOLOGICAL ASSOCIATION.

Seventeenth Annual Meeting, Held at Washington, May 1, 2, and 3, 1900.

The President's Address.—Dr. Abraham Jacobi of New York called the meeting to order and delivered the introductory address. The subject was "Cardiac Murmurs, Functional and Organic, in Infancy and Childhood." (See MEDICAL NEWS, p. 729.)

The Modern Physician's Duty to His Tuberculous Patients.—A paper on this subject by Dr. Frederick I. Knight of Boston was read by title. The following points are emphasized: (1) To make a positive diagnosis as early as possible. (2) To inform the patient of the gravity of the situation; not that he is consumptive, but that he is tuberculous and liable to become consumptive; but also that he has a good chance to recover if he pursues the right course. (3) To put the patient at once on the best road available in his particular case for an effort at recovery. This must vary immensely according to the nature of the case, the character of the patient, his family and other relations, and his financial condition. The physician should make up his mind, if possible, exactly what course to advise without discussing pros and cons of different propositions with the patient, but possibly consulting other members of the family. This involves the study of the whole question of residence at home or abroad, in a sanatorium or out of it, partial or total relinquishment of business, etc. (4) To provide that the patient shall be all the time under the care of a medical man familiar with the modern treatment of such cases.

The Construction and Management of Small Cottage Sanatoria for Consumptives.—Dr. Arnold C. Klebs of Chicago advocated concerted action of a national character with an underlying, carefully-studied plan to bring about lasting results. He described the work of the Pennsylvania Society for the Prevention of Tuberculosis and the Society recently organized for this purpose in Chicago, and referred to various sanatoria in the United States and abroad. Dr. Klebs insisted that, in addition to the usual regimen, institutions should provide an adequate occupation, *e. g.*, games, entertainments, lectures, etc., to relieve the monotony of the life in such institutions, and should not fail to provide some kind of work that may be useful to the patient after his discharge. Gardening, carpentering, and work in a manual training-school were suggested. Great stress was laid on the importance of an abundant pure air supply. The distinct advantage of certain climates, especially those of high altitude and southern latitude, over others nearer to the chief centers of population has often been claimed but never been conclusively demonstrated. The demonstration that equally good results are possible from the treatment at home, or near home, is to be received as a great blessing. Sunshine, rain and wind are the great natural purifiers of the atmosphere. It is easier to secure good, wholesome food near the cities. Dr. Klebs showed plans of several Continental sanatoria and also original plans prepared with the assistance of Mr. J. Gamble Rogers, architect, of Chicago, which were considered to be an improvement on those heretofore employed. The capacity is for 25 patients. The plan embraces three cottages, joined by two galleries. Dr. Klebs has been able to keep patients out-of-doors through the winter in Chicago where the season is not renowned for its mildness. Dr. Klebs is a believer in the use of water as an adjunct to treatment.

The antituberculosis movement which is now sweeping over the civilized world, led by crowned heads and supported by distinguished men, to be of lasting benefit must have a more substantial basis than the mere education of the public through written or spoken advice. The appeal for the erection of sanatoria should not be put at

the end of the program. Tuberculosis will never be stamped out by indirect measures alone. Improvements in public hygiene and the spreading out of the population of cities to rural districts by means of improved transportation will be a great aid in its limitation.

Dr. Stubbert of Liberty, N. Y., spoke strongly in favor of the cottage plan of hospital construction for the tuberculous and said that these patients do not like to be thrown too closely together. He does not employ exercise very much in the treatment, but had been on the watch for agreeable diversions out-of-doors. Amateur theatricals had been tried with success. The patients rehearsed out-of-doors and their minds were pleasantly occupied and diverted from their ailments.

Dr. R. C. Newton of Montclair advocated the plan of moving about, tramping, and especially the undertaking of a driving-tour as practised by the late Dr. Henry I. Bowditch.

The Degenerative Results of Deficient Ventilation.—This paper was read by Charles Denison, M.D., of Denver. After a general description of man's needs of air and the sources of impurity that he encounters, Dr. Denison claimed that there was something more needed to secure perfect ventilation which he termed "the life of the air;" that there is a vitalizing principle whose force is annulled by the imprisonment of the air by defective ventilation. This life of the air exists chiefly in its motion, which, with light, heat and electrical power, comes from the sun. Dr. Denison instanced the air of the Mammoth Cave in Kentucky as the deadest air he ever breathed, and he quoted largely from Dr. Angus Smith's work on "Air and Rain" in which are detailed investigations on similar lines.

Dr. Denison believes that tuberculosis has come here to stay and that it springs from, or is the outgrowth of, some unified cause which will account for its existence in cattle, horses, birds, and man. Legislation is needed to limit the minimum ventilation allowable in every place of assembly and for dairy-cows, horses, etc. The minimum of space for a living apartment should be 1500 cu. ft. per individual and a minimum ventilation, or change of air, of 2000 feet per hour per person. A course for the study of ventilation should be made a prominent feature in all advanced schools and colleges and the Government should carry out the many investigations which will help to determine both the best means and the proper and necessary limits of ventilation. This is one of the ways in which a National bureau or board of health could prove itself most useful. Dr. Denison urged the maintenance of a commission on ventilation of houses, public schools, factories and mines.

Dr. R. J. Curtin of Philadelphia suggested that the climate of Denver is changing and that the air is not so dry as formerly. The sprinkling of streets and the planting of trees and subsequent irrigation and increase of running water no doubt effect the quality of the air.

Dr. Denison, who had seen the population of Denver grow from 16,000 in 1873 to 170,000 in 1900, stated that he had nine or ten cases of tuberculous meningitis, a much larger proportion of cases of this affection than he would be likely to meet elsewhere.

Dr. James A. Hart of Colorado Springs could call to mind only one case of undoubted indigenous tuberculosis.

Some Phases of the Tuberculosis Problem in Colorado.—Dr. S. G. Bonney said that there has developed an increasing popular prejudice against the ordinary association with the consumptive and a beginning sentiment against the further importation of individuals afflicted with the disease, amounting to a somewhat ill-proportioned and ignorant crusade. There result embarrassing difficulties in the way of securing adequate accommodations for the consumptive, with much unnecessary humiliation, with lack of moral encouragement, to those entitled to every sympathetic consideration.

Dr. Bonney is in hearty sympathy with the health authorities and has contempt for the indifference of those who refuse to coöperate in the rigid enforcement of regulations tending to the restriction of the disease; but he is not in sympathy with an agitation not warranted by the facts and tending to create alarm. He is unable to accept the evidence presented to substantiate the alleged increase of consumption contracted in Colorado, as the data are altogether too meager to warrant such conclusions. The fact is that the actual number of cases originating in Colorado is not increasing in proportion to the population. In 1893 these numbered 49; in 1894, 51; in 1896 but two more than in 1895 and but 17 more than in 1893, in spite of an increase in that time of 26,000 in population; in 1899, despite an increase of 50,000 in population since 1893, the number of cases is but four more than in 1893 or .30 per cent. in 1899 compared with .36 per cent. of total population in 1893. Dr. Bonney believes that a factor of no inconsiderate importance is the strong inherited susceptibility of a portion of the younger population in Colorado. During the past seven years of all the cases reported to have died from tuberculosis contracted in Colorado nearly one-fourth were in children under four or five years of age, 85 per cent. of whom died of tuberculous meningitis. Dr. Bonney believes that the first requisite should be compulsory notification and a properly-conducted registration of all cases of tuberculosis. This not to imply isolation, personal humiliation or interference with social or business pursuits; quarantine for such a disease is neither desirable nor practicable in the interest of either the consumptive or the general community. The question of legislative interference with marriage and other matters involving the liberty of the consumptive and disturbing his relation to his family and society should receive no mention in official public communications as being at present both impracticable and unwarranted. It is more properly within the

province of the physician in his advisory capacity to expect such an influence as may be justified by individual circumstances.

Stomach Conditions in Early Tuberculosis.—Dr. Boardman Reed of Philadelphia said that in the incipient stage of tuberculosis flatulent dyspepsia with eructations and pyrosis, or heartburn, with or without gastric pain or nausea, are common symptoms. They may be due to lowered nerve tone or may be evidences of actual gastric involvement. Hyperchlorhydria and acid gastric catarrh are quite as compatible with a tuberculous infection as are the asthenic types of gastric disease. Clinical experience shows that in early tuberculosis there is present very frequently a condition of the peptic glands which contraindicates the administration of any considerable doses, by the stomach at least, of highly-stimulating remedies, such as carbolic acid, creosote and its derivatives, the mineral acids and most of the familiar stomachics. Dr. Reed cited a case which illustrated this and which also showed how tuberculosis for a long time may masquerade in the guise of a stomach-trouble. As to creosote different opinions of its usefulness are held by clinicians of equal ability. Whether the remedy does good or harm depends mainly on the condition of the stomach. Recent experiments prove that the oils markedly lessen the secretion of hydrochloric acid in the stomach. In the cases, therefore, in which the gastric functions are almost always depressed, as in the later stages of phthisis, cod-liver oil or much fat of any kind impairs digestion and injures the patient; whereas in cases of hyperchlorhydria, which are so often found in the earlier stages, the same remedy exerts a double influence for good, since here it tends to correct the injurious hypersecretion at the same time that it helps to fatten and strengthen the patient. In intermediate cases a moderate amount of oil may prove helpful for a time. An occasional analysis of the stomach contents may guide as to its further use. In doubtful cases, in which analysis of the stomach contents is not practicable, as well as in cases in which the gastric juice has been found to be about normal, Dr. Reed approves of combining creosote or one of its congeners with cod-liver oil so as to have the stimulating properties of the former neutralize the depressing influences of the latter upon the peptic gland. Another point made was that the muscular walls of the stomach lose their tone and there results a tardy evacuation of the contents with consequent stagnation and fermentation. This weakened motility must be overcome before tuberculous patients can get well. Instead of drugs, breathing exercises, especially in the open air, as hill-climbing, bicycling and rowing, are highly curative in conjunction with a diet which is at once digestible, nourishing and not too bulky. Massage of the abdomen can also do great good, except when the gastric glands are irritable and inclined to overaction. Intragastric faradism was advised.

Value of Tuberculin Test in Diagnosis of Pulmonary Tuberculosis.—Dr. J. M. Anders of Philadelphia read this paper. He said the extreme desirability of clearing the nature of latent forms and dubious cases by precise methods prior to the appearance of obvious signs and symptoms or the finding of the specific organism of the disease is universally conceded. Tuberculin holds a place with the Röntgen rays in diagnosticating pulmonary tuberculosis in its incipiency. Dr. Anders cited three cases in which the test was of great value. In the first, a lad of fourteen years, who had always been in delicate health, there was a history of four weeks of symptoms that were distinctly typhoidal in character and later a positive Widal reaction was obtained. At the first visit a physical examination revealed only a phthisical thorax. After the fever had declined an injection of 2 mg. of tuberculin gave a positive reaction. An X-ray photograph was then taken and showed slight, though decisive haziness. In the second case the diagnosis was made by tuberculin and at the necropsy six weeks later miliary tuberculosis following Pott's disease with beginning psoas abscess was found. In the third case, which occurred in a young man, aged nineteen years, fluoroscopic examination of the thorax and repeated examination of the sputum gave a negative result. Injection of 1 mg. of tuberculin responded positively. This patient's sputum afterward showed tubercle bacilli. The author believes that the reported failure of dubious cases to react may be due to error of administration. In his own experience a few failures would have resulted had he not increased the dose beyond the usual maximum. It is a well-established fact that a small percentage of cases of undoubted tuberculosis, especially advanced forms, have been found to be non-reactive. There are doubtless varying degrees of individual susceptibility to the action of tuberculin and it is likewise well known that cases of bone- and joint-tuberculosis require larger quantities than other forms of the complaint. Again, when reaction occurs in apparently healthy individuals, it has been pointed out by Trudeau that we should not forget that autopsies made on persons dying of other diseases show unsuspected foci to exist in from 30 to 40 per cent. of those examined. An imperfect reaction is also obtainable in certain cases of sarcoma, carcinoma and syphilis. Dr. Anders exhibited tables carefully prepared to show the practical utility of the test. Doubtful and undoubted cases were carefully separated. The percentage of reactions in patients known to be tuberculous was 78.36 per cent., while 71.89 per cent. of the suspicious cases also reacted. The more recent and extensive clinical tests in widely-separated parts of the world by competent observers have resulted in a practically unanimous verdict which emphasizes its superior value as an aid to diagnosis of incipient cases and in no small degree its apparent harmlessness. Dr. Anders has never noted personally or in recorded cases any bad effects, except in one case of Addison's dis-

ease cited by Head, in which a fatal termination occurred thirty-six hours after the injection of 24 mg. of tuberculin.

Dr. Quimby of New York advocated the use of tuberculin for diagnostic purposes and stated his belief that the unfavorable opinion formed from its use when first announced was due to the larger dose employed, *viz.*, 10 mg.

Dr. Denison inquired what should be designated as a characteristic reaction.

Dr. A. C. Klebs said that different tuberculins gave different reactions and that there should be a standard tuberculin in order to get definite and comparable results.

Dr. J. W. Brannan of New York had used tuberculin at the Hospital for Ruptured and Crippled in tuberculosis of joints and in arthritis of the joints and had found the test valuable.

Dr. E. R. Baldwin of Saranac said that 2 mg. in a joint case is a rather small dose; that it requires a larger dose in tuberculosis of joints than in pulmonary cases.

Stamina.—Dr. A. M. Bell of Brooklyn read a paper entitled "Stamina: With Special Reference to the consumption of Fat Food for Its Maintenance as a Preventive of Tuberculosis." Dr. Bell stated it as an axiom that the power of resisting the ordinary exciting causes of illness, including pathogenic microbes, depends upon one's state of health. Feebleness predisposes to disease. As to abstemiousness, one may overeat and yet abstain from some essential food necessary for the maintenance of health. Dr. Bell claimed that, other conditions being equal, tuberculous diseases are prevalent inversely to the use of fat of some kind as an article of diet. Inability to digest fat food is one of the features of the pretubercular stage. Tuberculous patients are liable to a dyspepsia due to the too exclusive use of farinaceous food. Dr. Bell advised the fuller use of butter and bacon. Fat is the chief article of diet in the Arctic regions. The Esquimaux who live on "toodnoo," a kind of butter made from the separated fat of reindeer, are nearly exempt from tuberculosis. Furthermore their resistance to fatigue and general muscular power is very great. Dr. Bell attributes the increase of tuberculosis among the American Indians to the gradual increase of farinaceous food as an article of their diet. The Gauchos of the South American pampas and the flesh-eating Mahometans of India were instanced as examples of powerful development by reason of their liberal diet of animal food. Dr. Bell claimed that meat should contain the natural blood of the animal and should not be allowed to drain away in slaughtering, as is sometimes practised.

During Dr. Bell's professional career, extending over a period of nearly sixty years, he has rarely known a family or an individual that was brought up on a liberal supply of butter and bacon to become tuberculous. The "hog and hominy" of the negro dietary in the days of slavery was a safeguard against tuberculosis, but their food has changed and consumption is ripe among them. Pork and bacon is not now a favorite or common dish among them. Everybody has learned that cod-liver oil is good for consumptives, but few seem to have learned that food of the same character, suitable for the table, is preventive of consumption.

Aneurism of the Heart with Thrombosis of the Left Coronary Artery.—Dr. Judson Daland of Philadelphia cited the case of a man, aged fifty-four years, who contracted syphilis twenty-seven years before death and one of whose children now shows signs of having inherited this disease. Two years before death an ulcer appeared upon the side of his tongue, extending from the top to the base, which yielded to specific treatment. He was a chronic alcoholic for thirty years. While in apparent good health he suddenly became unconscious, with marked cyanosis and coldness of the extremities, loss of radial pulse, indistinguishable heart-sounds, shallow respiration, contracted and non-responsive pupils, frequent desire to urinate, and great thirst. Death resulted in twenty hours. The autopsy showed dilated hypertrophy of the left ventricle, partial dilatation of the apex region of the left heart, the size of an English walnut, a large area of fibroid degeneration, especially envolving the interventricular septum; recent and old thrombi; localized and firmly adherent pericarditis; almost complete occlusion of the orifice of the right corner of the artery; extreme deforming endarteritis of both coronary arteries almost completely obstructing the right coronary and thrombosis of the left coronary artery.

Dampness of Soil as a Factor in the Production of Human Tuberculosis.—This was the title of a paper read by Richard Cole Newton, M.D., of Montclair, N. J. The author gave the histories of four families which came under his personal care in all of which there was no family history of phthisis; they represented American (1), German (1), and Irish (2); there were from two to ten cases of tuberculosis in each of these families. In all instances the houses were very damp and generally unhygienic. Dr. Newton believes that something besides direct contagion by the reception of the tubercle bacilli is necessary to establish the morbid process which is known as phthisis pulmonalis. He cited Squire and Kanthack who note the behavior of certain animals, such as guinea-pigs and white mice, which are ordinarily resistant to avian tuberculosis but can easily be infected after being kept for a time in a warm chamber at 33°-35° C. The struggle is, therefore, to be for sanitation rather than disinfection and isolation, against the surroundings of a people rather than against a microbe which can grow only when a predisposition is set up. The results of sanitarium treatment have been practically identical so that while a life in Colorado is desirable, it is not necessary in order to save at least a third of our incipient cases of phthisis. While sunlight and life in the open air, pure

milk and a wholesome occupation are necessary, a dry, properly-constructed cellar is just as essential to the alteration of the predisposition, so that the bacillus of Koch cannot gain a foothold in the human organism, as any of the means named. They should live away from swamps, cesspools, sluggish streams and all stagnant and unwholesome bodies of water. The question resolves itself into one largely of drainage.

Dr. Leonard Weber of New York referred to the insanitary condition of the tenement-house districts of New York. These must be gotten rid of if the disease is to be controiled. Dampness lowers the vital resistance but does not necessarily increase the susceptibility to infection.

Dr. N. S. Davis, Jr., of Chicago spoke of the unfavorable influence of bad ventilation not only of rooms but of the human lungs. Dr. C. L. Minor of Asheville said that while tuberculophobia has its utility it has grown excessively without a corresponding product of prophylactic measures. He referred to the negro huts of the South and the fact that the negro washerwomen sometimes become infected by washing the clothing of the sick people who frequent the resorts. The better classes of the population are also careless. As a rule the public are under-aerated. They should not be alarmed unless in a practical way. Physicians should look after their patients in this respect while they are well as well as when they are ill.

Dr. E. R. Baldwin of Saranac Lake said that the reason why damp houses favored the propagation of tuberculosis was because of the general law that moisture keeps the tubercle bacillus alive, while dryness kills it.

Dr. Daland of Philadelphia who had visited Iceland, referred to the recent spread of tuberculosis through the island which previously had been largely exempt. The bacilli were introduced from Norway and their propagation was favored by the dampness, the fogs and winds and the absence of light for long periods.

Subsequent History of Patients Apparently Cured by Antitubercle Serum.—A paper on this subject was read by Dr. J. Edward Stubbert. This was a further report on patients whose history was given two years ago. None of these cases have relapsed and marked improvement has resulted in 78 per cent. of the cases. Details of the cases were given in full.

The Phlebitis of Advanced Phthisis.—This paper was read by Dr. R. G. Curtin of Philadelphia. Several cases were reported which apparently showed the traumatic origin of tubercular disease. Blows and falls are not unusual causes and prize-fighters are liable to the disease.

Dr. R. C. Newton of Montclair questioned whether the proportion of cases of pure tuberculosis was large in the latter class. They were men frequently of very intemperate habits and liable to syphilis.

Dr. Babcock of Chicago, Dr. Coleman of Augusta and Dr. J. M. Anders of Philadelphia reported cases of phlebitis in phthisis.

Dr. Norman Bridge of Los Angeles cited the case of a man, twenty-six years of age, who had had tuberculosis of the left lung for two or three years and then developed an ideal phlebitis of the right groin extending downward, with pain, fever, swelling, and tenderness. A similar condition set in upon the opposite side and pursued an identical course.

Intrapleural Injection of Nitrogen Gas in Tuberculosis.—Dr. H. P. Loomis of New York read a paper on this subject. He has found nitrogen gas free from all objections, and almost non-absorbable after a lapse of from three to six months. All the general symptoms improve after its use, the expectoration is lessened, the appetite improves, weight increases and hemorrhage is invariably stopped. It does not cure but arrests the progress of the disease. That pressure on the affected lung is of advantage may be inferred from the fact that in cases of advanced tuberculosis with fluid in the pleural cavity, if removed by tapping, death often quickly follows. Three-fourths of the cases of primary pleurisy are tubercular. Dr. Loomis has never seen any bad results in any case treated by injection of nitrogen gas. One hundred to two hundred cubic inches may be used. If introduced into the left pleural cavity the heart is displaced beyond the median line. The respiration-rate is increased and the pulse-rate lowered. In one case he observed subcutaneous emphysema and the patient became excited and talkative.

Dr. H. L. Taylor of St. Paul reported an unfavorable experience in over a dozen cases and only temporary improvement in one case and he found that in no case did the splinting of the lung amount to anything at the end of two months.

Dr. R. H. Babcock of Chicago supported Dr. Loomis and reported that in the majority of cases treated in Chicago the results were satisfactory, improvement following in a majority of cases. He reported a case in which the symptoms were arrested after injections at intervals of four or five weeks for a year and the patient in the meantime was under the most unfavorable domestic surroundings.

Dr. Charles Denison of Denver referred to his method of strapping the chest with plasters on the affected side. These were held in place by being carried to a collar on the opposite shoulder. He corroborated the power of these measures to stop hemorrhage and lessen the size of a cavity.

Dr. J. Edward Stubbert has used nitrogen gas in hemorrhagic cases with success. The lung must be absolutely compressed or failure will resule.

The Hydriatic Treatment of Tuberculosis.—Dr. J. H. Kellogg of Battle Creek read this paper. It will appear in a future issue of the Medical News.

Splenic-Myelogenous Leucemia with Pulmonary Tuberculosis.—This was the title of a paper by Henry L. Elsner, M.D., and William A. Groat, B.S., of Syracuse, New York. The combina-

tion of pulmonary tuberculosis and leucemia is exceedingly rare; in the terminal stages of pseudoleucemia far-reaching tuberculous changes in the various organs of the body are frequently found. The case reported by Dr. Elsner was in an Irishman, a baker, aged forty years, with a distinct alcoholic history. There was malaise with increasing weakness, and a dragging sensation with pain and prominence of the abdomen. He grew pale and sallow and had night-sweats. Cough set in and he developed pleurisy without effusion. Tubercle bacilli were found in the sputum after February 20, 1900. The abdominal symptoms were due to an enormous spleen and an enlarged liver. The posterior upper portion of the left lung was consolidated. In the upper half of the interscapular region on the right side there was cavernous breathing. In the anterior surface of the posterior laryngeal wall there was deep tuberculous ulceration. The blood-counts between January 25th and April 16th, 1900, showed from 3,320,000 to 2,922,000 red cells and from 320,000 to 121,500 white cells per cubic millimeter. The hemoglobin decreased from 62 to 55 per cent. (Gowers). The red cells were pale and there were numerous megaloblasts. The myelocytes ranged from 38 to 16 per cent. and brand the case as one of splenic-myelogenous leucemia. There was a gradual and steady decrease in the total number of leucocytes but an increase in the percentage of polymorphonuclear neutrophiles, a decrease in the number of myelocytes and an increase in the number of lymphocytes as the tuberculous process advances. The interesting point is that with added infection of whatever nature there is likely to be a marked reduction in the number of leucocytes. Dr. Elsner summarized the cases of Quincke, Stintzing, Lichtheim and Baldwin, the only other cases on record so far as known.

A Case of Mural Endocarditis.—Harold Williams, M.D., of Boston read this paper. The case was one in which there were no murmurs in spite of extensive disease of the mitral valve. The patient, a woman, aged fifty-four years, had angina pectoris with dyspnea coming on after a short walk. She was put to bed where she remained until her death, a little less than three months later. During this period she had recurrent attacks of intense dyspnea, loss of pulse and collapse. Consciousness was retained throughout the attacks. The attacks became almost continuous but were invariably without pain, and the usual remedies quickly failed in turn to give more than transient relief. At no time were murmurs detected by any of the physicians in attendance. The autopsy showed a serous pleural effusion of the left side, a clot in a branch of the left pulmonary artery causing consolidation of the corresponding extent of lung tissue. The heart weighed nearly twice the normal amount. The mitral orifice was of normal size. The flaps showed slight diffuse thickening. The chordæ tendinæ were generally thickened and shortened in such a manner as absolutely to preclude closure of the valve. The endocardial surface of the ventricular wall below the posterior mitral flap was thickened, white and very opaque. The left coronary artery showed nodular projections throughout its course but none showed calcification. The right coronary from its origin showed a sudden diminution in size and was transformed into a fibrous chord through which the canal could not be followed. Microscopic examination of the affected area in the wall of the left ventricle showed a proliferative endomyocarditis. The case was one of generalized arteriosclerosis, affecting vessels of medium and small size particularly.

Dr. W. S. Davis, Jr., of Chicago reported a case of malignant endocarditis which had recovered, an occurrence which he had never previously witnessed. The patient was a man, twenty-eight years of age. The onset was slow and the fever was persistent. It was of obscure origin.

Dr. J. W. Brannan of New York reported a case of absence of murmur in spite of marked lesion of the mitral valve. The patient died very suddenly and at the autopsy the mitral valve was found markedly contracted. The patient first had a systolic murmur, then a presystolic murmur, and for a month before death there was no murmur whatever.

Dr. Jacobi of New York referred to a case in which there were remnants of endocarditis, small exudations with hard circumscribed deposits and slight thickening of the edge of the valve, but absolutely no murmur could be heard. In children particularly the diagnosis is liable to be difficult. In malignant endocarditis there may be large coccus deposits but no murmur, especially when the deposits are along the insertions of the valves. When the deposits are on the edge of the valves there is a murmur.

Dr. R. C. Newton of Montclair said that in the experience of Dr. E. G. Janeway, out of twelve cases that he had seen, one had recovered and in that case the condition was due to gonorrhea.

Dr. S. A. Fisk of Denver reported on some favorable terminations of endocarditis. In one of these, a child, an endocardial murmur was the first indication of a diphtheria; recovery from the cardiac lesion is complete. In Colorado physicians do not lay such stress on its being an unfavorable symptom as they formerly did.

Dr. R. H. Babcock of Chicago stated that we know very little about the cause of murmurs. They are useful guide-posts that point out the way to correct understanding of a given case. In functional cases they are not very important and we must rely on the secondary physical signs. An aortic diastolic murmur may be absent in aortic insufficiency.

Dr. Williams, in closing, said that no bacteriological examination was made in his case.

Exercises Suitable for Children Suffering From Heart Disease.—J. Madison Taylor, M.D., of Philadelphia made a plea for regulated movements, such as massage and the so-called Swe-

dish movements. Passive movements have a value out of all proportion to the results obtained by voluntary exercise. By passive movements we improve the peripheral circulation and promote central changes of a restorative nature. Medicines fail in many cases in which passive exercises accomplish much good. Dr. Taylor cited cases in support of his position.

Dr. Abraham Jacobi, in the discussion, said that it is impossible to relieve the heart when there is no peripheral circulation. The skin contains a large part of the blood of the body distributed through the fourteen, fifteen or sixteen square feet of the adult surface. Friction does good and when the circulation in the skin is reestablished the heart is relieved. He advocated rest and cold-water treatment. Under their use the dilated and hypertrophied heart grows smaller. By rest the myocardium has a chance to improve. Dr. Jacobi employs rubbing, massage, caffeine and strychnia in such cases. Massage should be administered by physicians or by those who know the anatomy of the muscles and lymph-ducts and who know how to use their fingers where others use their hands indefinitely. The muscles are too much neglected.

The Nervous System in Pulmonary Phthisis as a Basis for Treatment.—Thomas J. Mays, M.D., Philadelphia, read this paper. The author holds that phthisis is an exhaustion of the vital forces of the body in which loss of appetite, fever, night-sweats and other well-known symptoms accompany or precede the earliest implication of the pulmonary organs; he believes that the original trouble in the great majority of cases lies in the brain and nervous system and particularly in the pneumogastric nerves. That the vagi are primarily involved in phthisis Dr. Mays has shown in rather a large collection of cases in which confirmation was made *post-mortem*. Holding these views as to the etiology and pathology of phthisis, Dr. Mays discards all the usual remedies and employs those measures which stimulate the nervous system, such as strychnine, static electricity, quinine, capsicum, *etc.* He also employs massage of the vagi in the neck and subcutaneous injections along their course. The dose thus used was five minims of a two-and-a-half-per-cent. solution of silver nitrate, preceded by a similar dose of a cocaine solution. The technic was described. Dr. Mays has used silver nitrate injections in about two hundred cases of phthisis during the last nineteen months. The results were gratifying, the cough and expectoration were greatly relieved or ceased altogether, dyspnea and oppression of the chest were relieved; vomiting increased in a marked degree; the general strength improved. The effect on the physical signs was equally gratifying. This was particularly true of the gain in body weight. Dr. Mays believes that if this auxiliary method is combined with other good hygienic, dietetic and medicinal treatment the practical results will be greater than without that method, and he claims that the nervous system is the principal avenue through which pulmonary phthisis may be successfuly approached from a therapeutic standpoint.

The Inadequacy of the Physical Signs as Indicating the Gravity of a Pneumonia.—Andrew H. Smith, M.D., of New York read a paper with this title. The actual degree of involvement in a case of pneumonia is not always easily determined and the autopsy frequently brings unexpected revelations. The faintness of the respiratory murmur in health and the presence of overlying fat may obscure the initial crepitus as well as the later percussion dulness. Furthermore, the area of consolidation often falls far short of the area in which the toxin is being found. This outer zone may not present notable signs but is actively engaged in the formation of toxin and in this situation their virulence is greater than is shown in the cause of cultures taken from the center of the consolidated area. Preexisting morbid conditions, such as chronic kidney-disease, cirrhosis of the liver and pulmonary tuberculosis, exert a very unfavorable influence on the progress of a pneumonia. Consequently, too much stress should not be laid on the physical signs in estimating how sick the patient really is. Once the diagnosis is established the patient ought not to be exhausted by repeated physical examinations and consultants should, as a rule, accept the result of previous physical examinations and base advice on the general symptoms and aspect of the case.

The Association elected the following officers for the ensuing year: President, Dr. R. H. Babcock, of Chicago; first vice-president, Dr. A. C. Peale, of Washington; second vice-president, Dr S. W. Langmaid, of Boston; secretary and treasurer, Dr. Guy Hinsdale, of Philadelphia; member of Council, Dr. Abraham Jacobi, of New York.

It was decided to leave to the Council of the Association the choice of the place and date for the meeting of 1901.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXXVI. NEW YORK, SATURDAY, JUNE 9, 1900. NO. 23.

ADDRESSES.

THE PRESIDENT'S ADDRESS.[1]

BY W. W. KEEN, M.D.,
OF PHILADELPHIA.

Two duties seem to me to devolve on the President of the American Medical Association in his annual address: (1) To consider the condition of the Association, with any suggestions that may be made for improvement, and (2) to take up some subject of professional interest which may be properly considered before the chief representative medical body of the United States.

In pursuance of the former, it is a great pleasure to me to congratulate the Association on its marked prosperity. The American Medical Association now numbers about 9000 members. A large number, truly, but when we consider that there are over 100,000 regular physicians in the United States, it is strange and anomalous that this Association should comprise less than one in ten of these physicians. I call your attention to this important matter in order that every member of the Association during the coming year shall try at least to induce another fellow physician to join the Association and thus double its influence for good.

Journal of the American Medical Association.—One of the most important functions of the Association is the publication of *The Journal*. Here, again, I have only words of encouragement. The number of subscribers to *The Journal* is about 15,000—a number, undoubtedly, in excess of that of any other medical journal in the United States, and I suspect only surpassed by the *British Medical Journal*, which publishes over 21,000 copies weekly. But it is not only on the number of subscribers that the Association is to be congratulated, but especially on the quality of the papers published in *The Journal*. It is, however, not only idle words of vague praise that we should bestow on the trustees and the able editor of *The Journal*, but we should recognize that never before in the history of *The Journal* has it been so well conducted, its pages so filled with admirable original articles and its influence for everything that makes for the best in medicine so potent as at present.

The Rush Monument Fund.—Dr. Albert C. Gihon resigned at the last meeting as the Chairman of the Rush Monument Committee. It seemed to me that his successor should be a physician rather than a surgeon, and from Dr. Rush's native city. Accordingly, I appointed Dr. James C. Wilson to the vacancy.

The Committee report actually in hand a little over $11,000. This sum is too large to go backward, and it is not enough to go forward. In the hands of various State organizations, and possibly others, there are several thousands of dollars, I believe, which have been pledged to this fund. I recommend that action be taken, looking to the early completion of the fund. All the more is this suitable, when we remember that there will be erected in the city of Washington this year, or early next, a costly monument to Hahnemann, for which Congress has given a site.

The Antivivisection Bill.—Early in the session of the present Congress, there was introduced into the Senate, bill No. 34, commonly called the "antivivisection bill." The immense detriment that this would work both to man and animals was so evident that I deemed it my duty as your President to take the most active steps to prevent its becoming a law. I sent out letters to the president and secretary of every State medical society in the country, to prominent members of the profession in every State, to a large number of influential men in the profession all over the country, and to college presidents, and others who could direct public opinion, and by all means in my power strove to arouse a public sentiment against the bill. I wish to bear public testimony to the enthusiasm and the unanimity with which my appeals were received. The profession in every part of the country responded nobly and exercised a wide and, I believe, an enduring influence on senators and representatives in establishing and confirming their judgment against the inhumanity of any such bill.

In response to a communication addressed to the chairman of the Senate Committee on the District of Columbia, a hearing was granted in Washington before the subcommittee having charge of the bill, at which both the friends and the opponents of the measure were present and presented their arguments. Among those who spoke against the bill were Drs. William H. Welch,[1] Henry P. Bowditch, H. A. Hare, William Osler, Mary Putnam Jacobi, George M. Kober, Howard A. Kelly, D. E. Salmon, Brig.-Gen. George M. Sternberg, Surgeon-General U. S. A., Bishop Lawrence, of Massachusetts, and myself. Certainly a more able array of speakers could hardly have been obtained, and I wish in your name, and in the name of humanity, to thank them for their self-sacrificing help.

Although in two prior Congresses the Committee on the District of Columbia had unanimously reported in favor of the bill, I am happy to say to you that the present committee has so

[1] Delivered at the Fifty-first Annual Meeting of the American Medical Association, held at Atlantic City, N. J., June 5-8, 1900.

[1] The Journal, May 19th and 26th.

far changed its views that I have reason to believe that the bill will either slumber in committee or be reported negatively. While it is to be hoped that this is the end of the present bill, it is by no means certain that it is the end of the agitation of those who are so blind to the progress of medicine and, therefore, to the dictates of humanity, but, I have no doubt that the effort will be renewed at some future time. If this should take place, I commend to the then President of the American Medical Association the duty of opposing the bill with all the vigor which he can use.

Among the important contributions to antivivisection literature evoked by this discussion, none is more valuable than the letter addressed to the Chairman of the Committee on the District of Columbia, in opposition to the bill, by President Eliot, of Harvard College, which was presented to the readers of the Medical News in the issue of May 26th, page 832.

Coming from such a high source, I can not but feel that it will carry conviction, both by the force of its statements and the lucidity of its logic. I call your especial attention to the ground taken by President Eliot, that it is the antivivisectionists who are inhumane and cruel to the last degree, because they would condemn both man and animals to suffering and death by impending the progress of medical science.

Members of the American Medical Association.—By its constitution, the members of the Association consist (1) of delegates; (2) of members by invitation; (3) of permanent members, and (4) of members by application. I wish to call your attention to the desirability of limiting the members by invitation to foreign delegates, eminent foreigners whom the Sections may desire to invite to read papers and take part in the discussion, to members of the medical staff of the United States Army, Navy and Marine-Hospital Service, and to the occasional visiting physicians from our possessions outside of the limits of the United States proper. It has been the custom in most of the Sections to invite medical men of distinction who are not members of the Association to read papers before the Sections. Some of these gentlemen have been even openly hostile to the Association, and yet year after year have had the courtesies of the Association extended to them. They have availed themselves of these privileges and advantages and yet not only privately, but sometimes publicly, have expressed their hostility to the Association.

It seems to me that the time has now come when this practice should cease. Membership in the Association is open to every American, and any one who does not choose to avail himself of the privileges and advantages of membership by joining the Association should be debarred from them.

During the present year I have sent a courteous circular letter to each person so invited by the various Sections, but not a member of the Association, enclosing a form of application and inviting him to become a member of the Association. I am glad to say that a very large number have availed themselves of the opportunity of doing so. The Constitution prescribes that the members by invitation shall be invited by "the meeting after an introduction from and being vouched for by at least three of the members present or three of the absent permanent members;" and in the order of business, the third order is the "reception of members by invitation." No such formality, it seems to me, is desirable. The extending of such an invitation to distinguished foreigners and others that I have suggested may well be left in the hands of the Sections, with the exception, it might be, occasionally of persons of unusual distinction.

Section on Pathology.—One of the important features of the American Medical Association is to promote the scientific side of medicine. It has seemed to me that the Association was not fulfilling its duty to scientific medicine in one important particular. There is scarcely a more important branch of modern medicine than pathology and bacteriology, and yet no section for the consideration of these subjects is provided. Although it was not authorized by the Association, I had such confidence in your intelligent and hearty co-operation that I ventured to ask a number of gentlemen to act as a provisional or unofficial committee to organize a Section of Pathology and Bacteriology, under the chairmanship of Dr. Ludvig Hektoen, of Chicago. These gentlemen have ably performed their task and they have presented a most attractive program. You will be asked to officially authorize the formation of such a Section, and I can not doubt what your action will be.

In connection with this, I also appointed a provisional or unofficial committee on a pathologic exhibit, in charge of a committee, of which Dr. Joseph Stokes, Moorestown, N. J., is the chairman. Dr. Frank B. Wyman, Indianapolis, Ind., has acted as secretary of both committees. I but ask you to visit the adjoining exhibit to be convinced of how faithfully and intelligently this committee has performed its task. They communicated with a large number of medical schools, museums, and individuals and have met with a most hearty response from all sides. They did not deem it wise that the exhibit should be either by States or by institutions, lest there should be aroused a rivalry, which would in some sense smack of egotism and lead to future disaster; but asked all to subordinate their individual and institutional interests to the broad general interests of science.

The Annual Exhibit.—The management of the annual exhibit is a matter of considerable importance to the Association. The exhibit is an important financial aid to the local committee which has charge of the meeting of the Association.

So far as I know there are no rules governing the charges, the classes of exhibits, or rather regulations by which this committee may be guided.

Each new committee is a law unto itself. It has seemed to me that if there could be a permanent committee on the annual exhibit, this would be of great advantage, especially if the committee were made up, in part at least, of those who had had experience with former exhibits. It would seem to be desirable that each year the chairman or some other member of the committee on the last exhibit should be added to the committee to replace one of the earlier members, who would retire. I recommend, therefore, that such a committee, to have charge of the exhibit at the annual meeting, be appointed this year, this committee shall have power to add to its numbers and nominate a chairman who shall reside in the place at which the succeeding meeting is to be held, and as many other local members of the committee as may be deemed necessary to carry on the work. The general committee could formulate general rules governing the exhibit and the local committee could carry out the details.

The Sections.—The work of the Sections has been, heretofore, in many respects admirably done. The tendency to correlate the papers which are presented under certain specific heads, and to select one or more important topics for consideration, inviting a few distinguished speakers to open the debate, which is thus thrown open to all, has been marked in the last few years. The advantages of such a source are so obvious that I trust the chairmen, secretaries and executive committees of the various Sections will hereafter strive for even more important debates and more important results than have been thus far achieved. Room should certainly be reserved for a certain number of volunteer papers, but to allow the major part of the time of the Sections to be taken up by a mass of heterogeneous papers on unrelated topics would be a great misfortune.

The policy of *The Journal*, also, in connection with the various papers read before the Sections is an important one. Papers vary greatly in their merit and importance, and it would seem to me that to the trustees and the editor of *The Journal* should be confided the entire responsibility of selecting the more important papers for publication in full, and of presenting the less important in longer or shorter abstracts. The example of the *British Medical Journal* may well guide us in this matter.

I ventured to correspond with the chairmen and secretaries of the various Sections as to the hour of the Section dinners. Very frequently this has been fixed at nine o'clock, an hour which was too late for the usual dinner and too early for a second one. Moreover, when the dinners are fixed at so late an hour, if they are to be followed by after-dinner speeches the hour at which the Sections can break up and seek a much-needed rest is so late that it interferes seriously with the work of the succeeding day. Almost without exception, the officers of the Sections preferred the usual dinner hour, about seven o'clock, both for material and intellectual reasons. It is often difficult to arrange this matter with the hotels at which the dinners are usually given, but the Association, I think, might insist, as but a single evening is occupied by these dinners, that for the one occasion the hotels who profit so largely by the meeting should accommodate the Association in this matter.

Committee on the Thirteenth International Medical Congress.—Early last autumn Prof. William Osler, who had been requested to organize the American Committee on the coming International Congress, invited the President of the American Medical Association, and the Presidents of the various associations of medical specialists to form a committee to assist in organizing the International Medical Congress which is to assemble on August 2d in Paris. This Committee, and especially its chairman and secretary, have done the work exceptionally well. Of course, there is need of money for printing, postage, and clerk hire. At a recent meeting in Washington, the various societies represented by their chairmen, were invited to contribute $25 each toward the expenses, I recommend that an appropriation of $50 be made from the funds of the American Medical Association toward the expenses of this committee.

Endowment of Medical Schools.—Turning, now, from the affairs of the Association, I wish to say a few words in reference to a subject of paramount importance which I am sure will appeal to the sympathies of all present, namely: the need for endowments for medical schools.

The tide of charity in the United States has reached a remarkable height. The *Chicago Tribune* publishes an annual list showing that in 1894 the charitable gifts and bequests in the United States amounted in round numbers to $20,000,000; in 1895, to $29,000,000; in 1896, to $34,000,000; in 1897, to $34,000,000; in 1898, to $24,000,000; and in 1899, to the enormous sum of nearly $80,000,000.

But a small portion of this charity, however, has been bestowed upon medical schools. It is mostly to colleges, theological schools, hospitals, museums, and libraries, that the principal amount has been given. The cause for this, I think, has been chiefly the vicious method in which all our medical schools were formerly conducted. They were practically joint-stock companies, organized for the benefit of the faculties. As Professor Bowditch has said, one might as well expect the public to endow a cotton-mill as to endow such a school. The day of these private enterprises is now, happily, nearly past. The respectable schools of medicine are now conducted by trustees, a body of men wholly apart from the faculties, who manage the affairs of the medical school just as they would those of a university, taking control of the income and expenditures of the school, placing the professors and other teachers upon salaries, and conducting the affairs of the institution on broad lines of educational progress. Partly as a result of the influence of the profession exerted through the Association, the courses of study at the medical schools of to-day, and, therefore, the

necessities of the student, are so wholly different from those of twenty-five years ago that it may be well termed a new era in medical education. As a consequence of the broadening and lengthening of the medical course of study, the cost of medical education has enormously increased. The public at large does not at all appreciate this changed condition, and even you, members of the profession itself who may have graduated many years since, scarcely appreciate to its full value the difference. As a consequence, the fees of the students, which can scarcely be raised beyond the present amount, are wholly inadequate for providing a proper medical education, and the medical school appeals, as does the college and the theological and the technical school, for wise and liberal endowments in order to provide this suitable education. "There is no branch of education," says President Eliot of Harvard, "which more needs endowment. Medical education is very expensive, because it has become, in the main, individual instruction. Large lectures and crowded clinics are seen to be of really very limited application, so that year by year the medical teaching becomes more and more costly."

What were the necessities of a medical school twenty-five years ago? Two lecture-rooms, in which seven professors talked, a dissecting-room, and, if possible, a clinic, which was occasionally, but rarely, in a college hospital. Practically the instruction which the student obtained, with the exception of dissecting, was limited to "book-knowledge" and "ear-knowledge." The student was not brought into contact with any patients or any concrete facts, observations, or experiments. He only listened to what his teachers said about them. Millions were given to hospitals in which the sick were treated, but only sixpences to medical schools, in which the men who are to care for their future patients were trained. "Spain," says Lyman Abbott, "in the late war had nineteenth-century guns and sixteenth-century men behind them. We know what came." Our splendidly-equipped hospitals are the nineteenth-century guns. Insufficiently trained doctors are the sixteenth-century men. The time has certainly come when the "men behind the guns" must equal in efficiency the weapons with which they do the fighting.

To perform a tracheotomy and rescue a child suffering from diphtheria is a dramatic occurrence which appeals to every one. To conduct a long series of experiments in the laboratory, by means of which the cause of diphtheria shall be found and the necessity for a tracheotomy avoided, appeals only to the educated few; yet the service done by the operation is a service only to the one patient who may be rescued by the knife, while the other is a service to hundreds and thousands of patients who, for all time, will escape both the knife and the disease. Yet, such a series of experiments in preventive medicine brings no reward in money, a limited reward in fame, and only its largest reward in the consciousness of giving a great boon to humanity.

The era of the man who simply listened to what his teachers had to tell him and then went on his way, as a "rule of thumb" man, is, happily past. This is the era of the trained man and the trained woman, and training means opportunity provided by the community and time, labor and money given by the man.

Let us look for a moment at what a medical school now needs. It stands for two things: (1) "Thing knowledge," instead of "book-knowledge," and "ear-knowledge," teaching the facts of modern science, by scientific methods; that is to say, methods of precision. But (2) no medical school should be content simply with imparting the knowledge that exists. It should push back the boundaries of ignorance and, by research, add to existing knowledge.

In the accomplishment of the first duty of the medical school, there are required, first, didactic lectures. I am not one of those who believe that the day of the didactic lectures is past. "Never," said President Faunce, of Brown University, in his notable inaugural, "never shall we be able to do without the personality of the teacher, flaming with enthusiasm for knowledge, pressing up the heights himself and helping the student on."

In the 156 medical schools in this country there are, perhaps, over 1500 members in their faculties. In all of them are inspiring teachers flaming with enthusiasm, for a not inconsiderable proportion may properly be so described, and the influence of such enthusiastic teachers is felt by the entire class. One or two such men in every school make a good faculty. Besides the didactic lectures, a good working library and a reading or study room is a requisite. And it is a matter of no little encouragement that in the reports of the United States Commissioner of Education for 1898, 72 medical schools reported 151,433 volumes in their libraries.

The great difference between the modern method of teaching medicine and the older method consists in *laboratory instruction and clinical instruction*, both of which must be individual. Laboratories are very costly. They require buildings, equipment, and assistants. The number of laboratories required in the present day in a fully equipped medical school is astonishing. First, the dissecting-room—the anatomical laboratory—and along with this a laboratory of histology, and another which may be combined with it, a laboratory of embryology. Next, a physiological laboratory, in which each student will not become an accomplished physiologist, but will become familiar with physiological methods and be trained in exact and careful observation; a laboratory of chemistry and, combined with it, especially, a laboratory of physiological chemistry; in the department of materia medica, a laboratory of pharmacy, where the student will not only become a good pharmacist, but will learn the essentials of pharmacy so that he will not make, at least, gross mistakes, which, otherwise, would constantly occur. Still more important is a laboratory of pharmacology, in which he will learn the action of

drugs and be prepared rightly to use them. In obstetrics, a laboratory of practical obstetrics and obstetric operations is essential. In surgery, he needs a laboratory in which he shall be taught all the ordinary surgical operations. In pathology, he needs a laboratory of morbid anatomy, a laboratory of bacteriology, of hygiene. The mere statement of this catalogue of thirteen laboratories will enforce the fact that an enormous expense not only for the installation, but also for the running expenses, will be required. To show what one university abroad does, Professor Welch has stated[1] that the Prussian government expends, outside of the salaries of professors in the University of Berlin alone, over $50,000 annually. What American medical school can show anything approaching an endowment which will provide such a sum?

And what has not the laboratory done for us within the last few years. It has discovered the cause of tuberculosis, tetanus, suppuration, cholera, diphtheria, bubonic plague, typhoid fever, erysipelas, pneumonia, glanders, and a host of other diseases; it has shown us how to avoid all danger from trichina so that our entire commerce in hog-products is conditioned upon the laboratory; it has shown us how to banish suppuration, erysipelas, tetanus, and pyemia from our hospitals and reduce our death-rates after operation from 50 or 33 per cent. to 10 per cent., 5 per cent., 1 per cent., and often even fractions of 1 per cent.; it has given us a really scientific hygiene in which we no longer guess but know; it has shown us the rôle of the mosquito in malaria, of the rat in bubonic plague, of the fly in typhoid fever; it has given us the power to say to diphtheria "thus far shalt thou go and no farther;" it will give us the power to utter a pæan of victory over typhoid, cholera, bubonic plague, tuberculosis, yellow fever, cancer, and other such implacable enemies of the human race;—and yet there are those who would stay this God-given hand of help!

And the laboratory has had not only its devotees but its heroes. Listen to the story of but one. Dr. Franz Müller, of Vienna, was one of those who in his investigations of the bubonic plague in 1897 contracted the dreaded disease from the bacilli in his culture-tubes. When he became certain that he was infected he immediately locked himself in an isolated room and posted a message on the window pane, reading thus: "I am suffering from plague. Please do not send a doctor to me as, in any event, my end will come in four or five days." A number of his associates were anxious to attend him, but he refused to admit them and died alone, within the time he predicted. He wrote a farewell letter to his parents, placed it against the window, so it could be copied from the outside, and then burned the original with his own hands, fearful lest it might be preserved and carry the mysterious germ. Can you find me on any page of history a finer example of self-sacrificing altruism? Was ever a Victoria Cross more bravely won?

But the establishment of laboratories, with their attendant expenses, is not the only improvement in our medical curriculum. Every well-conducted medical school requires a large hospital in connection with it. Here must be installed again a fourteenth laboratory of clinical medicine in which all the excretions of the body will be examined, tumors studied, cultures and blood-counts made, or else the patients in the hospital, from the modern point of view, are neglected. It is not too much to say that a patient requiring such examinations, be he the poorest of the poor, has his case more scientifically studied, more exactly measured, more precisely treated than most rich patients in sumptuous homes.

Again, the individual instruction to which President Eliot referred is now carried out in all of our best medical school hospitals by the establishment of small ward-classes, by whom or before whom the patients are examined, prescribed for and operated upon by the professor or instructor, each student bearing a part; and so, by having his investigations directed, his powers of observation cultivated, his mistakes pointed out, his merits applauded, the student graduates from the medical school equipped as none of us, alas, ever had the opportunity to be. All of these laboratory and ward classes imply an enormous increase in the number of assistants, young men striving not only to perfect themselves, but by teaching, to forge to the front so that the best men will win the struggle for preferment.

Again, the course of study has been prolonged from two years, as it was until 20 to 25 years ago, to four years, and in addition the terms have also been lengthened. When I was a student the course of study consisted of two sessions of about 19 weeks each, or 38 weeks in all. Now the course consists, as a rule, of four sessions of 32 weeks each, or a total of 128 weeks, an increase of 90 weeks, nearly 3½ times as much as 25 years ago. In 1885, 103 schools had courses of two years, and 5 school courses of three years. In 1899, 2 schools had courses of two years, 10 of three years, and 141 of four years.[1]

It can be easily seen that from this additional time required another source of expense has arisen besides the increased number of assistants. The time given to teaching by members of the faculty, as a rule, has been more than tripled, as compared with twenty-five years ago. In addition to this, professors in charge of laboratories must practically give their whole time to the work and are precluded, therefore, from any income from practice. These men must receive salaries sufficient for them to live on.

Surely this statement of the difference between the education given twenty-five years ago, which required but little expenditure of money and resulted in considerable incomes, and the modern

[1] Higher Medical Education and the Need for Its Endowment. MEDICAL NEWS, July 21, 1894.

[1] Monographs on Education in the U. S.: No. 10, Provisional Education, p. 11. James Russell Parsons, Jr., Dept. of Education for the U. S. Commissioner to the Paris Exposition of 1900.

methods of education in the laboratory and the hospital, as well as the lecture-room, which require enormous expenses, is an ample reason for large endowments.

But, the function of the medical school, as I have said, should not be limited merely to the imparting of existing knowledge. No school is worthy of the name that does not provide for greater or less research work by which substantial additions to our knowledge may be made and the facilities and the results of the healing art made more efficient for the welfare of mankind. Twenty-five years ago there were practically few young men who were fitted for research work, especially laboratory work. Now every well-equipped school has attached to it, in one way or another, a score or more of young men who are eager for work, longing for the opportunities for usefulness and distinction if they can only obtain a bare living. When in my own school I look around me and see these young men thirsting for opportunities for usefulness and distinction, I am often heartsick at our want of facilities for this purpose, and I long with an intense longing for some wise and munificent friend of humanity who will endow post-graduate scholarships, fellowships and laboratories for just such an end. Our hospitals do a magnificent work in charity, helping the sick and the forlorn, the weak and the suffering in a way which appeals to the charitable instincts of our fellow-countrymen, and to this appeal they have responded most generously. *But I venture to say that the medical school which trained a Lister, a Pasteur, a Koch, has done more for humanity than all the hospitals of this country combined.* The modest laboratory at Würzburg consisted chiefly of a Rhumkorff coil, and a Crookes' tube—and Röntgen. Other Röntgens and Listers we have among us if we but knew it. These are the men who are the world's real illustrious heroes.

It is especially in these days that in America we need such researches, for our tropical possessions have brought us face to face with new problems which we can only justly meet by the most careful investigations. It is to our credit that several of our medical colleges have already established schools of tropical medicine, which show that the profession, as well as the public, are rising to the level of our responsibilities.

It is also a cheerful sign of the times that at Harvard a school of comparative medicine has been established, which will lead to other similar schools in connection with our medical colleges, for the broad study of disease both in man and in the lower animals. All such knowledge should be correlated, and we may well learn from the diseases of animals how to care for man, as thus far we have learned chiefly from the diseases of man how to care for animals. The endowment of this school with the modest sum of $100,000 is an omen of future good. So too, the somewhat similar school at Buffalo bids fair to add immensely to our knowledge and therefore to our ability to heal.

What now has the American public done for the medical school? Let us contrast it with the endowments in theology. Our academic institutions have such an enormous sum-total of endowments that I do not even consider these. Let us, however, compare theology and medicine, remembering that theology is almost wholly a literary study, dealing not with the facts of Nature, requiring no laboratories and no large corps of assistants and therefore conducted at a minimum of cost. In 1894[1] 84 theological schools reported endowments of $18,000,000, and 71 schools do not report this item; 19 out of 151 medical schools report endowments of $1,906,072. Five theological schools have endowments of from $850,000 to $1,369,000 each. Yet in 1899 there were only 8000 students of theology for whom this enormous endowment was provided, as against 24,000 students of medicine. Each theological student had the income of an endowment of $2250 provided for his aid, each medical student the income from $83. As against 171 endowed chairs of theology there are only 5 in medicine.

I do not grudge a dollar to the theologian, but I plead for his medical brother, that, with a vastly more expensive education he shall have a reasonable provision made for his training. I have already indicated to some extent the direction which these endowments of medical schools should take. They may be classed in three categories: (1) The endowment of professorships. By doing this the salary of the professor would be made available for the other wants of the school. The endowment may well take the form of a memorial, either of the generous donor, or, still better, of some distinguished former occupant of such chair whose name would always add luster to it. (2) The endowment of the laboratories which, as I have indicated, are so costly, both in their installation and in their yearly expenses. (3) The endowment of post-graduate scholarships and research fellowships, these being intended especially for those who will devote their time to original research. Students can not take much time for original research; their regular studies will absorb all their energies. Research must be done chiefly by young graduates under the direction of stimulating and energetic members of the faculty.

It is not, I trust, too much to hope, if not now, that in the near future the American Medical Association will set a fruitful example by giving each year "Scientific Grants in Aid of Research." The first object of the Association must be, necessarily, to place itself on a strong financial basis. It should own its own building, its printing and publishing plant, and, as soon as possible, should have a reserve fund of considerable proportions. Nothing conduces to the stability and conservativeness of any institution like a good bank balance. The British Medical Association has to-day an excess of assets over liabilities of nearly $380,000, chiefly invested in its building at 429 Strand, London. The American Medical Associa-

[1] U. S. Education Report.

tion has made a fair start with a surplus of over $27,000 last January, and, with its large, and, let us hope, rapidly increasing membership, it will before long assume a rank second only to the British Medical Association. Last year[1] the Scientific Grants Committee allotted £741, or somewhat more than $3500, for research work, distributed to three research scholarships, the holders of which were paid $750 each a year, and thirty-three grants in aid of research work, varying in amounts from $25 to $100. Among those to whom grants were made occur the well-known names of Beevor, Vaughan, Harley, Kanthack, Luff, Manson, Noel Payton, and Risien Russell. I should hope that the American Medical Association might even now begin by a modest appropriation, say of $500 a year, which should be allotted by the trustees, or by a special committee on scientific grants, after a careful investigation of the merits and the character of the person to whom such grants were made. No grant should exceed $100, or possibly even, at first, $50 in amount. The results of such grants would be not only absolute additions to our knowledge, but the cultivation of a scientific spirit which would permeate the whole profession and elevate its objects and aims.

In pleading for these endowments of medical schools, it is but a plea for a return to the profession of a tithe of what they have given. Two years ago I carefully investigated the value of the services rendered to the poor in the city of Philadelphia by the medical staff of the Jefferson Medical College Hospital alone, and I found that 129 medical men were then attached to the hospital, and their services, calculated on a very modern basis of the ordinary fees, I valued at over $500,000. To a profession which gives so freely of that which is most difficult to give, its own life-blood, surely the public for its own protection may give reasonable endowments to its medical schools. It will be returned to the community tenfold in better educated, better trained and more successful doctors. More devoted, self-sacrificing men and women they never can have.

GASTRIC HEMORRHAGE.*

BY WILLIAM L. RODMAN, M.D.,
OF PHILADELPHIA.

PERMIT me in the first place to express my profoundest gratitude to the Association for the distinguished honor conferred in placing the surgical oration for 1900 in my hands. It is with more than diffidence that I aprroach so great a responsibility, being keenly alive to my own shortcomings, and having for the nonce a quickened memory of the brilliant addresses made on former occasions by many of my illustrious predecessors.

Gastric hemorrhage of whatever nature was, until recently, looked upon as strictly a medical affection, and was treated on the same general principles as underlie the treatment of many other internal hemorrhages. This is still true of many, indeed, most cases of gastrorrhagia, but as I shall endeavor to show, is not the case with others which are treated by a combination of medical and surgical means and others still which should be met by prompt operative procedure.

Our purpose will be best subserved by enumerating the different varieties of gastrorrhagias, showing how they are to be diagnosticated, and giving the treatment to be pursued in the more important varieties. Hemorrhage from the stomach may result from ulcer of the stomach, duodenal ulcer, gastric carcinoma, cirrhosis of the liver, vicarious menstruation, post-operative hematemesis, purpura hemorrhagica, miliary aneurisms, aneurisms of the aorta and other vessels, leucemia, typhoid, yellow and other infectious fevers, valvular disease of the heart, and various kinds of traumatism.

Gastric ulcer is the most common disease of the stomach producing hemorrhage—occurring in 5 per cent. of the entire population, according to Ewald[1] and others high in authority. Hematemesis occurs in at least 50 per cent. of all cases of gastric ulcer, and many authorities estimate it as present in 80 per cent. It is, too, fatal in 8 per cent. of the cases in which it occurs, according to the conservative estimate of Leube,[2] and we can not question that it is indirectly fatal in a much greater number of cases by anemia and its remote consequences. Many authorities who might be quoted place both the frequency and mortality of hemorrhage higher than Leube does, and very few as low. Therefore, its prompt detection and proper treatment are of the greatest importance.

The recognition of gastric hemorrhage resulting from ulcer usually is readily made on account of the previous diagnosis in the case; but if the patient is seen at or subsequent to the hemorrhage for the first time, its association with the other classic symptoms of ulcer, particularly pain and vomiting after eating, leave little room for doubt. While there will be pain, vomiting, and gastrorrhagia in carcinoma of the stomach, the differences furnished by the two diseases are so marked that doubtful or border-line cases will be rare. The pain of ulcer is often relieved at once by emesis if it empties the stomach. This is not the case with pain and vomiting of carcinoma. Bleeding in carcinoma is rarely so free as in ulcer; the amount of blood lost being more frequent, in small quantities, and of the characteristic coffee-grounds appearance. It does not resemble pure blood, as it does in ulcer, even though mixed with food. The presence of hydrochloric acid—perhaps an excess of it, or hyperchlorhydria—in the ejected matter is as characteristic of ulcer as its presence and the presence of lactic acid are of carcinoma. Ulcer is more frequent in females under forty, whereas carcinoma occurs more commonly in men past middle life.

If an examination of the patient is allowable, the presence of a palpable tumor will be more

[1] Brit. Med. Jour., 1899, ii, p. 219.

*Abstract of Oration on Surgery delivered at the Fifty-first Annual Meeting of the American Medical Association, held at Atlantic City, N. J., June 5-8, 1900.

often encountered in carcinoma than in benign ulcer, but I would emphasize the fact that a decided tumor may, and did, exist in quite a number of the forty benign ulcers thus far excised.

Treatment.—Formerly the treatment of hemorrhage from gastric ulcer was uniformly by ice, astringents, and opium, combined, of course, with rest. This should properly be the treatment still for the first hemorrhage in all cases; for the second possibly; but not for subsequent ones, for recurring hemorrhage, like appendicitis, will sooner or later prove fatal, and should, like that affection, be treated radically; and to carry the parallelism further, the best time to operate is between attacks. With two hemorrhages coming close together we may assume that, as in appendicitis, there will be a third attack, and if anything is to be attempted surgically it should be done when the patient is in fairly good condition, and not in the collapse of hemorrhage.

Before taking up operative procedures it might be well to refer to the treatment of gastrorrhagia by copious enemata of hot water, as advised and practised with such happy effect seemingly by Tripier.[4] In several cases which have resisted all the usual medicinal and dietetic treatment, Tripier secured prompt and abiding results by hot enemata repeated twice or thrice daily. The water should be injected at a temperature of 112° to 120° F. There can be no doubt, he says, that the hemorrhage came from the stomach, duodenum, and points high up in the alimentary tract. Hot water acts reflexly.

Tripier has also found that hot enemata promptly check intestinal hemorrhage in typhoid fever, as it will bleeding from the rectum, sigmoid, and large bowel.

Plunging the hands in hot water will at times quickly arrest bleeding at the nose, as will ice applied to the head. This, surely, must be reflex. Another and good reason for using hot water per rectum in the manner advised by Tripier is, that if nothing more is done shock is combated in the best possible way, as it is easy to add salt to the water in proper proportion to make normal salt solution. Hot water should also be taken in small quantities by the stomach. It is my belief that it will be less likely to excite vomiting and more certain in its hemostatic effects than ice. If the bleeding is capillary or the open arterioles of very small size, prompt hemostasis may result; whereas, if an artery or vein of any size has been opened we may expect much less from any treatment which depends for its success on the formation of a firm clot in the mouth of the bleeding vessel, than we usually can in external hemorrhage.

In hemorrhage the result of disease, however, we have very generally a lateral opening made into the caliber of the blood-vessel, and the ability of the latter to contract and retract within its sheath is no greater, but actually less, than that of a vessel incompletely cut across. Occasionally, it is true, ulcerative action will as completely divide a blood-vessel as if it were done by a knife, but such cases are exceptional, as will be shown by a careful study of fifty-five fatal cases of gastric and duodenal hemorrhage collected and reported by M. Savariaud[5] in his very complete thesis.

Of fifty-five autopsies collected from various sources, and reported by Savariaud—none was operated upon—there were: Ulcerations of the splenic artery, 17 cases; ulcerations of the coronary artery, 6; ulcerations of the pancreaticoduodenal, 7; ulcerations of the gastric arterioles, 10; branches of the coronary vein, 2; other veins, 2; vessel not determined, 2; no vascular orifice visible, 4; vessel not mentioned, 4.

Hematemesis frequently occurs as the result of duodenal ulcerations, and as it is at times impossible to differentiate between gastric and duodenal hemorrhage, we have included the seven cases of duodenal ulcer. Furthermore, gastric and duodenal ulcerations frequently coexist and the treatment of both is essentially the same. The splenic artery and vein have been opened by the same ulcer, as occurred in the case of Gaillard.[6]

Contrary to what might with reason be expected, there is no constant relation between the size of the vessel and the amount of blood, or the rapidity with which it is lost. It is impossible, therefore, to diagnosticate with any degree of certainty the source of the hemorrhage, and an opinion at best is only a guess based on probabilities anatomic and pathologic. He who said, "the end of all philosophy is a learned doubt," must have been a medical man thinking of gastric hemorrhage.

The subjoined table is also from Savariaud.

Vessel	Cases	Sudden Death	Rapid Death	Survived
Heart	4	1	1	2 (3 days)
Aorta	2	1	1	1 (10 days)
Hepatic	2	1	1	1 (10 days)
Splenic	17	3	7	7 (2 to 8 days)
Coronary	6	1	3	2
Pancreaticoduodenal	6	1	3	2 (8 to 15 days)
Arterioles	10	1	1	8 (4 to 15 days)
Small Veins	4	1	1	2 (7 to 11 days)
Invisible Veins	3	2	1	1 (21 days)

It will also be seen from this table, based on autopsies where careful examinations were made, that death may be sudden in capillary hemorrhage, or delayed ten days when there is an opening into the aorta as large as a haricot bean—Grunfeld's case.

This uncertainty of diagnosis is a strong argument in favor of surgical intervention before it is too late to be of use. I would emphasize the fact as shown by the above table, which is based on accurate post-mortem examinations, that large and rapidly fatal hemorrhages may occur from capillaries.

Having exhausted all of the ordinary medical means for arresting hemorrhage should such cases be treated as external hemorrhage, viz., the bleeding vessels cut down upon and ligated? There is a sufficient number of cases on record to justify the statement that better results will be secured by judicious interference than by a policy of inaction hitherto invariably followed. By this I would not be understood as advocating the opposite plan of interference in every case—far

from it. Up to a certain point there is a substantial agreement between physicians and surgeons, and I may say here that the idea of arresting hemorrhage from gastric ulcer by surgical means occurred to a physician and a surgeon at the same time. In all cases of small but frequent hemorrhages, which slowly but almost surely destroy the patient, recourse should be had to timely operation. If there is at the same time gastrectasis, the indication for operation is absolute, as dilatation stretches the ulcer, prevents healing and favors bleeding.

The results, too, of operations for chronic hemorrhage have been more than encouraging, and should, without question, lead to earlier and more frequent surgical intervention. There have been thirty-one operations for frequently recurring, or what might be called chronic, hemorrhage, with six deaths, or a mortality of 19.3 per cent. This is, under the circumstances, an excellent showing when it is remembered that it represents but little more than the average mortality given in a large number of operations on the stomach for non-hemorrhagic ulcers. Mr. Robson[7] reports 188 operations for gastric ulcer—non-hemorrhagic and non-perforating—with a mortality of 16.4 per cent., which is about the same conclusion reached by Heydenriech,[8] Tricome[9] and others who have written on the subject. He (Robson) later on gives the mortality of operations for chronic hemorrhage as 10.5 per cent. Manifestly gastro-enterostomy, pyloroplasty, or other operations on the stomach should not give a better prognosis on account of the presence of hemorrhage as a symptom. The good showing now made for recurring hemorrhage will be still better when physicians generally recognize that if delayed operations are justifiable, early ones are better, and should, therefore, be encouraged at a time when the chances of success are correspondingly brighter.

Operations for acute hemorrhage in general do not so imperatively call for surgical intervention, but when this is said, it is saying nothing more than is true of external hemorrhage. In the present state of our knowledge, we can not say that operation should ever be done during the first hemorrhage or the ensuing shock. Likewise, if seen after the hemorrhage, when the patient is successfully rallying from shock, a policy of non-intervention is not only permissible, but best.

I am thoroughly convinced, from a careful study of all reported operated cases up to date, that none were operated on too early, but many too late. It is certainly the duty of the physician to summon surgical aid as soon as the second hemorrhage begins, if he has not already done so, that everything may be in readiness to seize upon a propitious time for interference before a third attack.

It is easy to believe that several cases in my tables were lost by delaying operation until after the third and fourth hemorrhage. *Per contra*, there have been quite a number of successful results after the second and third hemorrhage, operation having been done in a condition of extreme anemia in all of them, as in the cases of Roux, Robson, Caxin, Andrews, and two of Armstrong's cases. There have been thirty-two operations for acute hemorrhage with thirteen deaths or 40.6 per cent. mortality, a much better showing than was made by Mayo Robson, who reported a smaller number of cases, and included also among them cases of vicarious menstruation and post-operative hematemesis, neither of which has any direct etiologic or other connection with gastric ulcer.

Of the dozen methods practised, the three best are pylorectomy or partial gastrectomy, according to the site of the ulcer, gastro-enterostomy, and ligature *en masse* of the gastric mucosa. The first is ideal surgery, preventing possible perforation and malignant degeneration; the second is practical and oftentimes the best surgery, stopping hemorrhage and favoring cicatrization of the ulcer by putting the stomach at rest; while the third is frequently the most desirable way to end an exploratory gastrotomy when the site of the bleeding vessel was unknown until the stomach was opened. Each method has given good results, but for many reasons the second has been preferred in a majority of instances, and of the many ways of performing gastro-enterostomy the posterior or Von Hacker's method with the Murphy button has been, and should be, generally chosen. Resection, if practicable, is best, but gastro-enterostomy would not only arrest the bleeding, but usually delay the inevitable end, and bring about a decided amelioration of all the distressing symptoms. Indicated as it often is in advanced carcinoma without hemorrhage, the presence of the latter as a symptom should be an additional reason for surgical intervention.

Cirrhosis.—Hemorrhage into the stomach is a frequent symptom in cirrhosis of the liver, and death resulting therefrom can not be considered as rare. Preble,[10] of Chicago, has recently reported 60 cases of fatal hemorrhage, 3 in his own practice, and 1 in that of a colleague and 56 collected from literature. The diagnosis in all was verified by autopsy. After a careful analysis of these, a full history of each being given, he draws some interesting and striking conclusions: "(1) Fatal gastro-intestinal hemorrhage is an infrequent but not rare complication of cirrhosis of the liver. (2) In a great majority of the cases the cirrhosis is atrophic, but it may be hypertrophic. (3) In one-third of the cases the first hemorrhage is fatal; in the other two-thirds the hemorrhages continue at intervals of over a period varying from a few months to several years, the maximum given being eleven years. (4) In one-third of the cases the diagnosis can be made at or before the time of the first hemorrhage. In the other cases the diagnosis can not be made at all or only after a few months or years, during which time other symptoms of cirrhosis have developed. (5) Esophageal varices are present in 80 per cent. of the cases and in more than one-half of the 80 per cent. the varices

show microscopical ruptures, and it is probable that many other ruptures would be found if the varices were tested by injection of air or fluid. (6) Fatal hemorrhages occur in cases which show no esophageal varices, and they are probably due to the simultaneous rupture of many capillaries of the gastro-intestinal mucous membrane. (7) The hemorrhages in this class of cases are usually preceded by other symptoms of cirrhosis, but the first symptom may be a fatal hemorrhage. (8) In 6 per cent. of the cases which show esophageal varices was the cirrhosis typical, *i. e.*, showed ascites, enlarged spleen, and subcutaneous varices."

Treatment.—It has been suggested that as esophageal varices are the cause of a large per cent. of the gastrorrhagias complicating cirrhosis, pressure should be made on the ruptured varix or varices by introducing a rubber bag into the esophagus and distending it with water or air. This suggestion, so far as I know, has not been carried out. The objections that one can urge against it are manifold: (1) It is questionable whether pressure can be sufficiently protracted in this way to be of benefit. (2) In only 6 per cent. of the cases showing esophageal varices was the cirrhosis typical, and therefore easily diagnosed. It is certainly unsafe to formulate a treatment which at best has only a chance to reach a comparatively small number of cases. (3) The esophageal veins are part of the systemic, while those returning blood from the gastric mucous membrane are of the portal circulation.

There can be no reasonable doubt, however, that operations for gastric hemorrhage in cirrhosis have a less promising future than the same procedures in bleeding ulcer; for in the former there is in addition that general hemorrhagic tendency that makes bleeding from any situation most difficult to arrest. No operation has as yet, so far as I know, been deliberately performed where the diagnosis of cirrhosis had been made. Several of the cases reported and operated on as hemorrhagic ulcers may have been—probably were—instances of cirrhosis.

Vicarious Menstruation.—There has been a more or less general sentiment, if not positive conviction, on the part of a majority of the profession, that vicarious menstruation may manifest itself in the way of hematemesis. Such was, too, until recently the general teaching, and there are not wanting those who still believe in the possibility of such an occurrence. If it does happen one would naturally think that it would be in young women whose ovaries and tubes have been removed, or in women submitted to hysterectomy, the appendages being left, and who can not therefore, menstruate in the natural way. I have written to fifty prominent gynecologists and surgeons to learn if they had seen, and if so how frequently, instances of vicarious menstruation showing itself by hematemesis following removal of the appendages, uterus, or both. Nearly all have answered, and it is a significant fact that only two have reported—each a single case—affirmatively. Yet these operations are very common, one of them having been for many years probably the most frequently practised surgical procedure. Many of the writers have expressed a positive conviction that vicarious menstruation does not occur. It would seem, therefore, that what has hitherto been a vague impression with most of us is not corroborated by a careful examination of a large number of cases, where it should if it ever occurs.

Post-Operative Hematemesis.—I can not find, in any of the text-books on surgery at my command, reference to post-operative hematemesis. It must therefore be rare.

Mayo Robson,[12] in his Hunterian lectures, states that he has encountered it in seven cases of his own, two being fatal, and refers to a similar experience of Eiselberg, who reported to the surgical society in Berlin the details of six cases. It is significant that nearly all of those reported by Robson and Eiselberg were instances of operations on the intestines, omentum, and structures adjacent to the stomach. The anesthetic could not have been responsible for the vomiting of blood, for in one of Mr. Robson's cases cocain was used, and a cholecystotomy for carcinoma of the bile-ducts completed in fifteen minutes. In several others there was no vomiting after the operation. Robson states that in six of the cases the omentum was ligated, and in another it was probably contused. He also says that "in an experiment on an animal multiple hemorrhages into the stomach followed twisting of the omentum."

I have, with the assistance of Drs. Burns and Woody, experimented on four dogs, endeavoring to cause hemorrhage into the stomach, if possible, by rapid and severe traumatism not applied to the stomach itself but without success.

Of the fifty surgeons written to, only nine have seen post-operative hematemesis. Three operators, Johnston of Richmond, Parish of Philadelphia, and Wathen of Louisville have had one case of gastrorrhagia following hysterectomy. All occurred within a week after operation, one being fatal. Clarke and Noble of Philadelphia have each seen fatal hemorrhage from duodenal ulcers after operation. The former does not give the exact nature of the operation, but it was intrapelvic. Noble states that his patient was a woman about 60, operated on for ventral hernia. Hemorrhage that was quickly fatal occurred on the tenth day after operation. Autopsy showed a marked duodenal ulceration. Noble and Wathen have each had a fatal case of hemorrhage after nephrorraphy. Noble operated on both kidneys in a young woman. Death occurred on the twelfth day, as a result of hemorrhage from the stomach and bowels. No autopsy was allowed. Wathen's patient was a highly neurotic young woman. She began vomiting blood more than a week after operation, and died two or three days later. There was no autopsy. Johnston has also reported cases of hematemesis following operations for ovarian tumor with a twisted pedicle, suppurating ovarian cyst, strang-

ulated hernia, and extra-uterine pregnancy. The first three were fatal and accompanied with general peritonitis; the last recovered. Three others have seen post-operative hematemesis, but it followed operations on the stomach itself; these were apparently cases of secondary hemorrhage, and are, therefore, excluded. I have been particular to make inquiries as to the frequency of hematemesis after hernia operations, as Robson and Eiselberg have both seen it. Of fifty surgeons written to only two have encountered it, and one of the cases was a strangulated hernia with general peritonitis. The other was the case operated on for ventral hernia, and who died from a demonstrated duodenal ulcer.

In more than a hundred herniotomies—strangulated and non-strangulated cases—I have never encountered it. The sum total of all the hernia operations done by the fifty surgeons to whom I have written must be many thousands, and yet but two cases of post-operative hematemesis are reported, and each has been satisfactorily explained, one patient dying of peritonitis following strangulated hernia, the other from a duodenal ulcer demonstrated by autopsy. All of the cases seen by Robson and Eiselberg followed intra-abdominal operations, such also being the case with all post-operative hematemesis reported by American surgeons, excepting two cases where nephrorraphy had been done. In doing nephrorraphy the peritoneum may, in the first place, be incautiously opened by the the most careful operator, and secondly, there is always a considerable amount of traumatism necessary to force the kidney into the lumbar incision. It is not, therefore, difficult to understand how a hematoma may easily be produced by the great abdominal pressure oftentimes necessary to bring the kidneys into view, and how, furthermore, this extravasation may occasionally cause sapremia, septicemia, or peritonitis according to circumstances. All septic conditions favor disintegration of the blood-corpuscles and predispose to hemorrhage from mucous surfaces. The gastric mucosa is particularly liable to congestion in conditions of sepsis, both on account of the marked tendency of the thin and more or less disintegrated blood to settle in the internal organs, and the vomiting and retching so frequently present.

We have in this a satisfactory explanation of the rare hematemesis following abdominal operations, and have shown that even violent traumatism to the omentum, intestines, spleen, pancreas and liver did not produce immediate hemorrhage into the stomach in any of the dogs experimented on, and it does not seem unreasonable to suppose that delayed hematemesis will usually depend on disintegration of the blood due to sepsis.

CONCLUSIONS REACHED AFTER A STUDY OF TYPHOID FEVER AMONG THE AMERICAN SOLDIERS IN 1898.[1]

BY VICTOR C. VAUGHAN, M.D.,
OF ANN ARBOR, MICH.;
PROFESSOR OF HYGIENE IN THE UNIVERSITY OF MICHIGAN; LATE MAJOR AND DIVISION SURGEON, U. S. V.

IT is well known that typhoid fever prevailed extensively among American soldiers assembled at state and national encampments during the brief war between the United States and Spain in 1898. In August of that year a board consisting of Major Walter Reed, U. S. A., Major E. O. Shakespeare, U. S. V., and the writer, was appointed at the request of the Surgeon-General of the United States Army, for the purpose of ascertaining the causes of the existence and spread of typhoid fever in the national encampments, and of suggesting means of its abatement. In accordance with instructions, this board visited the national encampments and inspected most of the regiments. While doing this, we interviewed medical and line officers, and obtained as far as possible the sanitary and medical history of each regiment. After completing this tour of inspection, we spent about eighteen months in going over the medical records of these commands. In this work we have accumulated a vast amount of information, which we have embodied in our final report to the Surgeon-General. Since much of this information may be useful to the profession, and as the report is not likely to be published soon, I have concluded that I can not do better than present some of the more important results reached in this investigation, as follows:

1. *Every regiment in the United States service in 1898 developed typhoid fever.*—This is true of both volunteer and regular commands. I am aware of the fact that some regiments have claimed freedom from typhoid fever, and it is true that the sick reports of more than one command fail to show any evidence of this disease; but by carefully tracing the sick to hospitals, we have been able to find one or more cases of typhoid fever in every regiment. The claim is made by an assistant-surgeon of one of the Pennsylvania regiments that there was not a case of typhoid fever in his command, but the records of the Philadelphia hospitals show that certain cases sent from this regiment proved to be typhoid fever. It is true that this regiment, which was engaged in guarding powder-works in New Jersey and Delaware, had relatively few cases of typhoid fever, but it did not altogether escape this disease.

2. *More than 90 per cent. of the volunteer regiments developed typhoid fever within eight weeks after assembling in the state encampments.*—It is impossible to fix any exact date on which

[1] Abstract of Oration on State Medicine delivered before the Fifty-first annual meeting of the American Medical Association, held at Atlantic City, N. J., June 5-8, 1900.

the several regiments assembled at their state encampments. However, as the first call for troops was issued April 20, 1898, it must follow that at the earliest all regiments assembled at state encampments during the last week of that month. Bearing this in mind, our report will show that the great majority of the volunteer regiments developed one or more cases of typhoid fever within eight weeks after assembling at the state encampment.

3. *Most, probably all, of the regular regiments developed typhoid fever within less than eight weeks after going into camp.*—When war with Spain was proclaimed, the total strength of the standing army of the United States was 27,000 officers and men. These troops were scattered at about 100 military garrisons. All of the soldiers were well housed, and their quarters were, from a sanitary standpoint, in good condition. At each garrison, the water-supply was above suspicion, and the disposal of waste was such as not to endanger the health or the life of the soldiers. There was no epidemic at any post, and the army was reasonably free from infectious diseases except those of venereal origin. The number of cases of typhoid fever among the 27,000 officers and men during the first four months of 1898 was distributed as follows: In January, 9 cases with 1 death; in February, 3 with 1 death; in March, 4 with no deaths; in April, 6 with 1 death. During the last week of April and the first week of May, 1898, the regular regiments were assembled in national encampments and placed under canvas.

4. *Typhoid fever not only appeared in every regiment in the service, but it became epidemic, both in the small encampments of not more than one regiment, and in the larger ones consisting of one or more corps.*—The statement has been made that the epidemics of typhoid fever in our national encampments in 1898 were due to crowding together large numbers of men. The Third North Carolina Volunteer Infantry, at its isolated post at Fort Macon, N. C., developed typhoid fever before it was sent to Knoxville, where it became a part of the Second Division of the First Army Corps.

When we reached Knoxville, Tenn., in our round of inspecting the troops, we were informed that the Fourth Tennessee was encamped near that place, where it had been since mobilization, and that it was wholly free from typhoid fever. A personal investigation showed the following facts: This regiment assembled June 28th, although it was not mustered into United States service until about the middle of July. On August 12th Ernest Martin, who had not been well for a week preceding this time, was admitted to the regimental hospital. On August 15th he was furloughed, and on September 11th he died at his home in Nashville, Tenn., of typhoid fever. From the date of this first case up to the time of our inspection (Sept. 14, 1898) there had been in this regiment not less than 11 well-marked cases of typhoid fever, although none had been so diagnosed by the regimental surgeon.

5. *Typhoid fever became epidemic in camps located in the Northern as well as in those located in the Southern States.*—Some medical officers have placed stress on the fact that Northern men were transferred to the Southern States in the summer time, and have attached considerable importance to the influence of non-acclimatization in the production of the epidemics of typhoid fever. In answer to this, we need only call attention to the fact that the Fifteenth Minnesota, Thirty-fifth Michigan and the Two Hundred and Third New York furnished large numbers of cases of typhoid fever, practically all of which developed before they crossed the Mason and Dixon line. There is nothing more certain than that the prevalence of typhoid fever among the troops in 1898 was not due to the geographic location.

6. *Typhoid fever is so widely distributed in this country that one or more cases are likely to appear in any regiment within eight weeks after assembling.*—We have no reliable data concerning the extent to which typhoid fever prevails in this country, but from the number of deaths due to this disease, we can fairly estimate the number of cases. Such estimations show that with this disease as prevalent as it is throughout the country, it is more than probable that in any organization of 1,300 men of military age, taken from private life and held together for two months, one or more cases will develop.

7. *Typhoid fever usually appears in military expeditions within eight weeks after assembly.*—The histories of the Galeaka-Gaika war of South Africa, the Zulu war, the Afghan, Egyptian and Nile campaigns all confirm this statement. Similar experiences are recorded in the history of mining camps in various parts of the world.

8. *The miasmatic theory of the origin of typhoid fever is not supported by our investigations.*—There are still some who believe that typhoid fever is due to a poison or miasma given off from the earth in gaseous form. I would not mention this obsolete theory were it not for the fact that while inspecting the camps we found intelligent medical officers who believed that some intangible local condition inherent in the place was an important factor in the production of the epidemic. There is apparently in man a tendency to believe in the evil genius of locality. He is prone to attribute many of his misfortunes to indefinable conditions surrounding the place in which he has suffered. As I have stated, no fact in our investigations has been brought out more prominently than the demonstration that locality was not responsible for the epidemics.

9. *The pathogenic theory of the origin of typhoid fever is not supported by our investigations.*—Murchison proposed this theory of the origin of typhoid fever. This author makes the following statement: "Typhoid fever may be generated independently of a previous case by fermentation of fecal and perhaps other forms of organic matter." Translated into terms of modern medicine, this theory is founded on the

belief that the colon germ may undergo a ripening process by means of which its virulence is so increased and altered that it may be converted into the typhoid bacillus, or at least may become the active agent in the causation of typhoid fever. Many French, English and American army medical officers believe that typhoid fever may originate in this way. Rodet and Roux, of the French army, have stated their belief that outside of the body the colon bacillus acquires "typhigenic" properties. Surgeon-Captain Davies has expressed his belief in this theory, and some of the medical officers in the American army have also given it their adherence.

I believe that the results of our investigations controvert this theory conclusively. In the first place, we have been able to show that the specific poison of typhoid fever was introduced into every one of our national encampments, and with the disease as widespread as it is in this country, I believe that we have good reasons for the claim that one or more men already specifically infected with typhoid fever enlisted in nearly every command. There is, therefore, no necessity of resorting to the theory that the colon bacillus may be converted into the typhoid germ. Moreover, all the known facts of experimental bacteriology are at variance with this theory. So far as the supposition that simple diarrhea may develop into typhoid fever is concerned, I may state that in my opinion our investigations conclusively prove that this is not true.

10. *Our investigations confirmed the doctrine of the specific origin of typhoid fever.*—As has already been stated, we have been able to trace the introduction of typhoid fever into every one of our national encampments and into the majority of the regiments. In the case of a few commands about which there is some uncertainty as to the men bringing the typhoid infection from their homes, I may state that in all of these there was ample opportunity for the introduction of the specific poison from other commands.

11. *With typhoid fever as widely disseminated as it is in this country, the chances are that if a regiment of 1,300 men should be assembled in any section and kept in a camp, the sanitary conditions of which were perfect, one or more cases of typhoid fever would develop.*—I have already stated my reasons for belief in the above given proposition. In such a camp, however, the disease would not become epidemic, and ultimately it should disappear altogether.

12. *Typhoid fever is disseminated by the transference of the excretions of an infected individual to the alimentary canals of others.*—It is more than probable that many individuals may for a while carry and eliminate the specific bacillus of typhoid fever without themselves developing the disease. It is now a well-known fact that persons who have recovered from typhoid fever may for a long time continue to carry and excrete the specific poison. It has also been shown that the longevity of the typhoid bacillus is much greater than is generally supposed.

13. *Typhoid fever is more likely to become epidemic in camps than in civil life because of the greater difficulty of disposing of the excretions from the human body.*—In fact, the whole question of the prevention of typhoid fever in armies is largely one of the disposition of the excretions.

14. *A man infected with typhoid fever may scatter the infection in every latrine of a regiment before the disease is recognized in himself.*—It must be evident from this that the only way in which typhoid epidemics can be with certainty prevented in armies is by the complete disinfection of the stools of all, both the sick and the well.

15. *Camp pollution was the greatest sanitary sin committed by the troops in 1898.*—In our history of the different regiments given in our report, we have had too frequent opportunity to call attention to the fearful pollution that existed in many camps. We have stated that fecal matter was deposited on the surface about the camps at Chickamauga and at other national encampments. Much of this filth must have been specifically infected with typhoid fever. Sinks were frequently overflowed by heavy rains, and their contents were distributed on the adjoining surface.

16. *Some commands were unwisely located.*—While there is no evidence that many of the places selected for national encampments could be called unhealthful, it is true that some of them were not suited for camp sites. Some regiments at Chickamauga, as we have shown in our report, were so located that they received the drainage of other regimental camps. There was certainly no sufficient excuse for this.

17. *In some instances the space allotted the regiments was inadequate.*—I am forced to conclude that there were line officers in the First and Third Army Corps whose efficiency might have been enhanced by some knowledge of camp hygiene.

18. *Many commands were allowed to remain in one site too long.*—There were regiments at Chickamauga that did not move a tent from the time of arrival in May until that of departure late in August.

19. *Requests for change in location made by medical officers were not always granted.*—As an illustration, I will refer to the official records of the Fifth Pennsylvania. This command reached Chickamauga Park on May 20th, and was unfortunately located on low ground. Requests for change in location were repeatedly sent in during June and July. The earth became muddy, the camp received the washings from other camps above, the sinks rapidly filled with water and overflowed, and yet requests for change in location were unheeded until August 12th, when the regiment was allowed to occupy a new camp two miles to the west and on a higher piece of ground.

20. *Superior line officers can not be held altogether blameless for the unsanitary condition of the camps.*—As we have already seen, some of the regiments were improperly located from a sanitary standpoint. This was done by superior

line officers, and sometimes in the face of protests from the medical officers. The medical officer can only recommend; the line officer may command. We think it unfortunate that no adequate instruction is given in hygiene in our national military school. It does seem that line officers should at least know enough of this subject to be able to recognize the importance of reasonable requests and recommendations made by medical officers.

21. *Greater authority should be given medical officers in matters relating to the hygiene of camps.*—It is of the greatest importance that more authority be granted medical officers in all matters pertaining to the hygiene of camps. Certain men in the medical corps should be selected to do the duties of sanitary inspector, and these should be chosen on account of recognized ability in this particular line. The sanitary inspector should make his reports in duplicate, one copy of which should be presented to the commander in charge of the troops, while the other should be forwarded to the Surgeon-General. When the line officer in command fails to comply with requests made by a medical inspector, he should state in writing the reasons for non-compliance, or at least he should in writing acknowledge the receipt of the recommendation.

22. *It may be stated in a general way that the number of cases of typhoid fever in the different camps varied with the method of disposing of excretions.*—This is well illustrated by the methods of disposing of fecal matter and in the number of cases of typhoid fever in the three divisions of the Seventh Army Corps. The First Division was most uncomfortably located at Miami, Fla., from the last week in June until the second week in August. On the last-mentioned date it was removed to Jacksonville, where it joined the other divisions. During a part of its stay at Miami, and during the entire period of its encampment at Jacksonville, water-carriage was employed for this disposal of fecal matter. In the Second Division the tub system was employed. By this method infected fecal matter was scattered all through the camp. In the Third Division regulation pits were used. The number of cases of typhoid fever was smallest in the First Division, and greatest in the Second Division.

23. *The tub system of disposal of fecal matter as practised in the Second Division of the Seventh Army Corps is to be condemned.*—Of all the methods for the disposal of fecal matter practised in the national encampments in 1898, I regard this as the most unsatisfactory.

24. *The regulation pit system is not a satisfactory system of disposing of fecal matter in permanent camps.*—Especially is this true in hot weather. It is a very difficult thing to have soldiers appreciate the necessity of keeping fecal matter covered. As I have elsewhere stated, in many camps orders were issued requiring each man to cover his stool as soon as deposited, but we did not inspect the pits of a regiment in which we did not find exposed fecal matter. Moreover, in the camps in 1898 flies swarmed so numerously that the first droppings of fecal matter were often covered with them before the act of defecation was completed. The pit system may be employed when armies are on the march, and stopping at one place for a few days at most, but even then they were sources of danger, and it is quite impossible to prevent the spread of typhoid fever in camps in which this method of disposing of fecal matter is employed.

25. *Our board has recommended that in permanent camps where water-carriage can not be secured, all fecal matter should be disinfectant and then carted away from camp.*—For this purpose we have made a special recommendation that galvanized troughs containing milk of lime be used for the reception of all fecal matter, and that the contents of these be removed daily by means of the portable odorless excavator. I am aware of the fact that this method of disposing of fecal matter will be attended by increased cost, but I am confident that it will greatly lessen the number of cases of typhoid fever.

26. *Infected water was not an important factor in the spread of typhoid fever in the national encampments in 1898.*—There probably were local water-supplies that became specifically infected with the typhoid-fever bacillus, but infected water was not the great factor in the causation of this disease.

27. *Flies undoubtedly served as carriers of the infection.*—My reason for believing that flies were active in the dissemination of typhoid fever may be stated as follows: (*a.*) They swarmed over infected fecal matter in the pits and then visited and fed on the food prepared for the soldiers at the mess tents. In some instances where lime had recently been sprinkled over the contents of the pits, flies with their feet whitened with lime were seen walking over the food. (*b.*) Officers whose mess tents were protected by means of screens suffered proportionately less from typhoid fever than did those whose tents were not so protected. (*c.*) Typhoid fever gradually disappeared in the fall of 1898 with the approach of cold weather, and the consequent disabling of the fly. It is possible for the fly to carry the typhoid bacillus in two ways. In the first place, fecal matter containing the typhoid germs may adhere to the fly and be mechanically transported. In the second place, it is possible that the typhoid bacillus may be carried in the digestive organs of the fly and may be deposited with its excrement.

28. *It is more than likely that men transported infected material on their persons or in their clothing, and thus disseminated the disease.*—In some of the commands it was customary to detail men from the line every morning to serve as orderlies at the hospital. These men went to the hospitals, handled bedpans used by persons sick with typhoid fever, and at night returned to their comrades. The most of them were wholly ignorant of the nature of infection and the methods of disinfection. In fact, at one of the division hospitals we saw orderlies of this kind go from

the hospital and partake of their midday lunch without even washing their hands. These men handled not only the food which they ate, but passed articles to their neighbors. It seems to me that a more certain method for the dissemination of infectious disease could hardly be invented.

29. *Personal contact was undoubtedly one of the means by which the infection was spread.*—The truth of this statement will be more evident after an inspection of the chart showing the distribution of the different regiments. On making such an inspection one must be impressed with the fact so plainly evident that men who were closely associated developed typhoid fever simultaneously.

30. *It is probable that the infection was disseminated to some extent through air in the form of dust.*—The shell roads through the encampment at Jacksonville were ground into the finest dust by the heavy army wagons. The scavenger carts carrying the tubs filled with fecal matter passed along these roads, and their course could often be traced by bits of feces falling from the tubs. Other vehicles ground up the fecal matter and dust together, and the winds disseminated these particles here and there. Men inhaled this dust; it was deposited on their food, and men ate the dust. Having seen these things, I am inclined to the opinion that infected dust was one of the factors in the dissemination of typhoid fever. I am aware of the fact that complete desiccation soon destroys the typhoid germ, but dust is not always completely desiccated.

31. *A command badly infected with typhoid fever does not lose the infection by simply changing location.*—I do not mean to say that it is not advantageous for a regiment badly infected with typhoid fever to change its location. On the other hand, in our history of the Second Division of the First Army Corps, we have shown that such change is of advantage and may be followed by a reduction in the number of cases; but mere change in location is not sufficient to stamp out the disease in a command after it has become widely disseminated. The histories of many regiments show this to be true.

32. *When a command badly infected with typhoid fever changes its location, it carries the specific agents of the disease in the bodies of the men, in their clothing, bedding, and tentage.*—This was shown by the fact that when commands changed location, leaving behind all their sick, and when they went to places free from infection, the disease continued with them.

33. *After a command becomes badly infected with typhoid, change of location, together with thorough disinfection of all clothing, bedding and tentage is necessary.*—Even when disinfection is carried out, the command will not altogether lose its typhoid infection, because some of the men will carry the germs of the disease in their bodies.

34. *Even an ocean voyage does not relieve an infected command of its infection.*—This is shown to be the case in the study of various commands that went to Cuba and Porto Rico.

35. *Except in cases of most urgent military necessity one command should not be located on a site recently vacated by another.*—This principle holds good even when the vacating regiment is not known to have suffered from any infectious disease. This axiom in military hygiene was frequently violated during the summer of 1898. In many cases of the state encampments the regiments that responded to the second call were located on sites recently vacated by commands that had preceded to the national encampments.

36. *The fact that a command expects to change its location does not justify neglect of proper policing of the ground occupied.*—The filthy condition of some of the regimental camps at Chickamauga was explained on the ground that each regiment expected to be called to the front in a few days, and therefore neglected camp sanitation. A camp site should be thoroughly policed up to the moment of vacating it. This should be insisted on as a matter of military discipline, and camp commanders should regard proper attention to the sanitation of the sites occupied by their troops as one of their highest duties, and its neglect as a crime.

37. *It is desirable that the soldiers' beds should be raised from the ground.*—In some of the regiments at Camp Alger the tents were never floored. On inspecting these commands in August we found dust several inches deep in the tents. During the day-time, in fair weather, the blankets were taken out, and men, possibly with their feet soiled with infected material, walked around in this dust, and at night threw their blankets down on it and there slept. This was both insanitary and uncleanly.

38. *In some of the encampments the tents were too much crowded.*—This was true both of the space allotted the tents and of the number of men occupying each tent. In some instances the tents of the same company were so close together as to leave no space between them, and those of two adjacent companies were crowded together back to back.

39. *Medical officers should insist that soldiers remove their outer clothing at night when the exigencies of the situation permit.*—With from twelve to sixteen men in a tent, all sleeping in the clothes worn during the day and possibly with some of them soiled with infected fecal material, the effect on the general health certainly could not have been beneficial, and the possibility of the dissemination of the infection must be admitted.

40. *Malaria was not a prevalent disease among the troops that remained in the United States.*—We have shown in our report that blood examinations for the plasmodium of malaria made by competent men at Chickamauga, Knoxville, Camp Mead, and Jacksonville, show that malaria was a rare disease among the troops that remained in the United States.

41. *The continued fever that prevailed among the soldiers in this country in 1898 was typhoid fever.*—There is no evidence that any other con-

tinued fever was found among the troops that remained in the United States. One surgeon claims that dengue prevailed in his regiment at Chickamauga. I think it quite impossible for dengue to have prevailed in one regiment, while all other troops of two army corps encamped at the same place escaped this disease. It was claimed by some that the continued fever prevalent at Chickamauga differed from typhoid, and that it was a disease peculiar to the place; it was designated "Chickamauga fever." That the continued fever prevalent in our camps in 1898 was typhoid fever is demonstrated by the following facts: (*a.*) When the temperature-curve was not vitiated by the use of antipyretics, it was that of typical typhoid fever. (*b.*) The fever was not broken or arrested by the administration of quinin. (*c.*) The death-rate was that of typhoid fever. (*d.*) Whenever a post-mortem examination was made, and the total of these examinations was considerable, the characteristic lesions of typhoid fever were found.

42. *While our investigations show that coincident infection with malaria and typhoid fever may occur, the resulting complex of symptoms does not seem to be sufficiently well defined and uniform to be recognized as a separate disease.*

In our report we have devoted a special chapter to this subject, and I will be compelled to refer those desiring detailed information to this.

43. *About one-fifth of the soldiers in the national encampments in the U. S. in 1898 developed typhoid fever.*—Among 44,803 officers and men in regiments of the First and Third Army Corps, the records of which we have carefully studied, the number of cases of typhoid fever according to our estimate was 9660. This is equivalent to 21.56 per cent. In the Fourth Army Corps the percentage seems to have been somewhat less. However, the records of some of the regiments of this corps were not well kept, and we can not be so positive concerning the number of cases.

44. *Army surgeons correctly diagnose a little less than half the cases of typhoid fever.*—The total number of probable cases of typhoid fever among the regiments studied at Chickamauga was 9660. Of these 4068 were diagnosed typhoid fever either by regimental or hospital surgeons. Most of the cases improperly diagnosed were sent to general military hospitals, or to civil hospitals with the diagnosis, "malaria." In 80 out of 85 cases sent from the Fifth Maryland to civil hospitals in Baltimore, the diagnosis was changed from malaria to typhoid fever. Of 98 cases sent from the Eighth New York to hospitals in New York City, all were recognized as typhoid fever by the physicians in each of the hospitals, while the majority of these had been entered on sick reports under other diagnoses. The failure of regimental surgeons to properly diagnose many cases of typhoid fever is easily explained. Orders required, very properly, that every man sick for forty-eight hours should be sent to the division hospital. It will be seen from this that the cases were not under the observation of the regimental surgeon for a sufficient time for him to make a diagnosis. There is also some excuse for the failure of the surgeons at the division hospitals to recognize all the cases of typhoid fever. Many of the less severe of these cases remained in hospitals for a short time, and were furloughed home, or forwarded to some general hospital.

45. *The percentage of deaths among cases of typhoid fever was about 7.5.*—Of the 9660 cases already mentioned as occurring among certain troops at Chickamauga, 713 died. This gives a death-rate of 7.38 per cent. This corresponds closely with the death-rate for typhoid fever in those places in which most accurate records have been kept. In the city of Hamburg, during the years 1886-87, there were 10,823 cases with a death-rate of 8.5 per cent. Brand has collected 19,017 cases treated by cold baths with a mortality of 7.8 per cent. Of the 2293 cases treated in some of the larger hospitals in this country in 1897, 9.24 per cent. died. Further details concerning the mortality in typhoid fever are given in our report.

46. *When a command is thoroughly saturated with typhoid it is probable that from one-third to one-quarter of the men will be found susceptible to the disease.*—I am inclined to believe, but desire to state it as an opinion, that typhoid fever disappeared in some of the regiments only after all the susceptible material had been exhausted. This was probably true in all regiments which had 400 or more cases.

47. *In military practice typhoid fever is often apparently an intermittent disease.*—This fact is shown especially in the study of the Eighth New York. Please bear in mind that I state that typhoid fever is apparently an intermittent disease. I do not mean that the apparent intermissions are afebrile: I only mean that the men sick with this disease had periods of improvement which were so marked that regimental surgeons often returned the men to duty, probably at the request of the men themselves.

48. *The belief that errors in diet with consequent gastric and intestinal catarrh induced typhoid fever is not supported by our investigations.* This belief, which was formerly held by many, is founded on false conclusions arising from erroneous conceptions of the etiology of the disease. Moreover, the early symptoms of typhoid fever are often confounded with those of simple gastro-intestinal catarrh.

49. *The belief that simple gastro-intestinal disturbances predispose to typhoid fever is not supported by our investigations.*—Our studies have forced us to come to the following conclusions concerning the relation between typhoid fever and preceding temporary disorders, including those diagnosed as diarrhea, enteritis, gastro-enteritis, gastroduodenitis, intestinal catarrh, gastro-intestinal catarrh, gastric fever, and simple indigestion: (*a.*) The temporary gastro-intestinal disturbances of May and June had but little if any effect on subsequent infection with typhoid

fever. (*b*) The temporary gastro-intestinal disturbances of July and August, instead of predisposing to typhoid fever, gave a certain degree of immunity against subsequent infection with this disease.

50. *More than 80 per cent. of the men who developed typhoid fever had no preceding intestinal disorder.*—In 2763 cases in which this point was especially investigated, 2356 were not preceded by any intestinal disorder.

51. *The deaths from typhoid fever were more than 80 per cent. of the total deaths.*—The percentage of deaths of typhoid fever to total deaths is not so high if we accept the diagnoses given in the official reports.

52. *The shortest period of incubation in typhoid fever is probably something under eight days.*—This statement is founded on data obtained by a study of typhoid fever among the hospital corps, men and women nurses at Chickamauga. The details are given in our report.

53. *One who has lived in a camp in which typhoid fever is prevalent is liable to develop this disease any time within eight weeks after leaving such a camp.*—The particulars bearing on this statement are given in the history of the Fifth Pennsylvania.

MEDICAL PROGRESS.

Statistics and Operative Treatment of Rectal Carcinoma.—J. Pichler (*Archiv f. klin. Chir., Bd. 21, Hft. 1, 1900, p. 220*) discusses this subject. The observations are made from the various methods of approaching the site of disease, namely, bloodless divulsion of the sphincter ani (Simon); circular incision of the anus (Lisfranc); posterior division of the sphincter (Diefenbach); posterior linear incision with preservation of the anus (Kocher); resection of the coccyx (Kocher); resectionof the sacrumin part, unilaterally (Kraske), transversely (Bardenheuer and Rose), obliquely (Hochenegg); temporary resection of the sacrum and coccyx (v. Heineke, Levy, Schlange, Kocher, Hegar, Rydygier); parasacral division of the soft parts of the sacrum without resection of bone (Zuckerkandl, Wölfler, Schelky); vaginal approach (Liermann). The oblique method of Hochenegg is the one carefully compared with all the others. This operator had in all 110 cases of carcinoma of the rectum treated in this way with the following results: There were but 10 deaths, distributed as follows, capillary bronchitis, gastro-intestinal hemorrhage, cerebral embolism, internal incarceration. These four are no more attributable to this type of operation than to any other severe surgical procedure and should, therefore, not be counted as affecting the statistics. The other six may be ascribed directly to the technic, although here again are two fatalities due to hemorrhage from varicose veins about the vagina. If these are discarded the final four deaths all due to sepsis, make the percentage 3.4; if counted the record is 5.04 per cent. Of 583 reports of all known forms of operation 81 died making the proportion 14.3 in the hundred; of the purely perineal avenues of approach 217 records were collected, 37 deaths or 17 per cent. The value of Hochenegg's method of sacral resection is claimed to be in the wide exposure of the field and the perfect drainage obtained. In no case was the bleeding from the bone margins a factor. The review of the subsequent histories of these cases gives the following data: Ten deaths more or less directly connected with the operation; 14 patients disappeared from view; 40 died of relapses with or without metastases, with an average prolongation of life of 21.4 months (individually these 40 lived as follows, 7 about one year, 12 over one year, 16 over two years, 3 over three years, 1 over five years, 1 over eight years); 8 further cases died of intercurrent disease (of these 2 of tuberculosis in about one year, 1 of psychosis after one year, 2 of apoplexy in about eight years, 1 of pneumonia after three years, 1 of cancer of the tongue after eighteen months; 1 of endocarditis in four years); 15 have partial subsequent histories, but it is certain that 4 of them lived three years, 2 after six years; 32 are still living (of these 5 over three years, 2 after four years, 3 over five years, 3 after six years, 1 over eleven years, 1 after twelve and three-quarter years, making 29 living after three years or more, the remaining 3 are living less then three years after the operation. If we stop to figure out the percentage of those living three years or more we find 52 cases which can not be counted (10 deaths, 14 without subsequent history, 8 lost sight of about the third year, 20 who had not yet reached the third year, although still alive), leaving 67 cases among which are the 29 above three years, 43.3 per cent. A word must be said about the continence of the rectum after the operation. First, complete control after simple suture, 5 cases; after invagination of the upper into the lower segment and suture, 24 cases; after spontaneous closure of a fistula, 3 cases; after plastic treatment of the same, 2 cases. Second, a sacral artificial anus was established from before backward in 50 cases, from rupture of the suture line in 27 cases. Third, the anus was made in its usual site after ablation of the sphincter in 8 patients. The great majority of the complete-control cases followed their ordinary avocations. Two women had children normally after the the operation. Another series of them had bougies passed for a variable time. One acquired a sacral hernia which was controlled by apparatus. Two patients complained of weakness and pain about the sacro-iliac joint. Those with artificial anus soon acquired skill in management and went quite comfortably about their work. The author's experience with recurrences was that these always began in the periproctitic tissue and by pressure and direct extension made colostomies necessary. Occasionally, the cancer extended between the bowel and the bone and gave other

terrible outward manifestations. Even these cases had been benefited because the involvement of nerves, urethra, bladder and other organs had been postponed, as is not the result of simply doing a colostomy early as a palliative measure. As to the etiology of these cases, 72 were males, 47 females; age limits twenty-one to seventy-two years; ages predominating forty to sixty; out-door work was the commonest vocation; two were brothers each operated on within one year; one was treated for carcinoma of the rectum and a year later for carcinoma of the tongue; one young woman appeared to have acquired it by using for enemata the same douche nozzle as her cancerous mother; pronounced alcoholism was frequent. In addition to rectal cancer Hochenegg has used this method in 49 other cases with 8 deaths, distributed as follows: Malformations, prolapse and stricture of the rectum, retroversions of the uterus, cystic tumor of the parametrium, myomata and carcinomata uteri, sacral tumor, pelvic abscesses, and dystopia of the kidneys.

Sterilization of Catgut.—E. Saul (*Arch. f. klin. Chir.*, 1900, *Bd. 21, Heft 1, p. 285*) says that chemical causes of suppuration may be present as well as bacteriological. Under these must be remembered: (1) Ptomains in the gut itself which may be best destroyed by boiling alcohol. (2) Fatty substances covering the catgut during manufacture. Boiling alcohol will remove these more completely than soap and water. (3) Argentic salts, which are present in catgut impregnated by the method suggested by Credé. (4) Corrosive sublimate suppuration in virtue of soaking the gut in its solutions. It is impossible to remove it from the substance of the gut because it is chemically combined therewith. Carbolic acid has no such affinity. This acid may be dissolved out by pure alcohol. If evaporation occur the concentration resulting may approach toxic limits. It is entirely true that experimentally bichloride of mercury is of higher disinfecting power than carbolic acid, but the experiments of the former involve an error, while those of the latter show none. One is consequently subjected to an unavoidable disappointment if disinfection is founded on a corrosive sublimate method. Jacobi, working under Rosenbach's direction, destroyed with boiling alcohol in fifteen minutes anthrax spores, which resist boiling water about twelve minutes. For this reason shorter exposures were not attempted. Hofmeister killed the bacillus subtilis with boiling alcohol in two hours. This germ withstands boiling water one and a half to two hours. The conclusion is almost inevitable that boiling in alcohol is almost as effective as boiling in water.

Histology of Leucocytes and Spores.—Continuing the research work with his new stain, K. Nakanishi (*Münch. med. Woch.*, May 15, 1900) adds the following to complete his former article: The best criterion of the vitality of leucocytes is the intensity with which their nuclei take up the stain. By this method it has been found that 3-5 per cent. of the polynuclear leucocytes of normal blood show beginning degeneration, while in shed blood leucocytes with undegenerated nuclear protoplasm could still be demonstrated after four weeks, provided proper preservation was obtained. The cell-division of bacteria and the genesis of their spores could be well studied with the new stain. The nucleus forms an hour-glass shape and soon divides and the daughter-nuclei will migrate toward the poles of the cell which now swell and also undergo division through the development of a partition in the middle. When unfavorable circumstances exist, a differentiation in the cell-protoplasm will occur since half of this will remain unchanged while in the other half the chromophilic matter will concentrate itself about the nucleus leading to an apparent swelling and elongation of this. A membrane forms and the mass will lose its affinity for the dye and appear like a minute fat-droplet. The uninvolved protoplasm of the original cell will be more and more encroached upon by the growth of the spore which soon becomes free.

The Loss of Hair.—Alopecia, although sometimes depending largely on hereditary influences, nevertheless in a majority of cases is probably due to a curable disease of the scalp and, hence, the statistics and treatment in regard to this condition given by G. T. Jackson (*Med. Record*, May 26, 1900) are especially interesting. Detailed information is given of three hundred cases in private practice and the following inferences were drawn: It is very probable that the loss of hair is much more frequent among men than women and although bachelors seem especially prone to this misfortune personal pride no doubt influences the statistics somewhat, and it is not likely that the married or single state has any influence in producing baldness. A great majority of the patients lead indoor lives and this, when coupled with worry and nerve-strain, is a predisposing, if not a determining, cause of baldness. Sixty-six per cent. of cases began before the thirtieth year and it would seem if one passes this age without showing signs of incipient baldness, the chances for keeping the hair intact are very much increased. As to the causes of the loss of hair heredity is a predisposing factor in a majority of cases and a determining cause in some. All debilitating diseases predispose to loss of hair and dandruff in some form is the exciting cause in over seventy per cent. Positive results in the treatment of this condition were obtained by the use of precipitated sulphur, ten per cent. in a good cold cream, with or without either salicylic acid, three to five per cent., or extract of jaborandi, a dram to the ounce. An ointment composed of ammoniated mercury gr. xx., calomel gr. xl., in an ounce of vaseline is also of value. Resorcin in solution with alcohol and a few drops of castor oil is recommended by some. After dandruff has been checked massage is very useful in stimulating the growth of

the hair. The sulphur preparations are used once every day for three days and then the head is shampooed. The ointment is then applied every second day for ten days and continued twice a week for some time. Resorcin is used at first in three- and then five- or ten-per-cent. solutions night and morning.

Mammary Epithelioma and Tuberculous Peritonitis.—Le Dentu and Morestin report the following case (*Revue de Chirurgie*, 1900, p. 425): The patient, an Englishwoman, aged twenty-seven years, demi-prostitute, appeared April, 1897, at the Broussais Hospital; she was tall, thin, and emaciated; there was a history of menstrual irregularities and syphilis; otherwise no illnesses. Breasts, always abnormally small, were suddenly attacked by violent enlargement with pain, discomfort and dragging weight; within two days their volume had increased about ten-fold and after two weeks in a stationary state were first seen. On examination they were in marked contrast to the emaciated patient, uniformly tense, enlarged to the size of the head of a six-year-old child. Their skin was slightly modified, somewhat rosy, thin, tense, transparent, showing the veins beneath much engorged. Palpation showed beneath slightly movable skin, each breast firm to hard, uniform surface, no lobulations, depressions, fluctuation or softening, no circumscribed outline and no gland-tissue differentiated. This was incorporated in the extensive infiltration, which was movable on the deep parts. No axillary nodes. No secretion present in the nipples. No subjective symptoms. The diagnoses offered were inflammatory infiltration, acute bilateral mastitis and fulminating carcinoma. The last appeared most probable, but hardly agreed with the hyperacute onset. Under gentle pressure in one week the size and hardness decreased, but again relapsed finally to improve again. During these changes there were no systemic manifestations. After a few weeks these acute conditions had disappeared when many small hard irregular nodular partially-fixed masses incorporated with the gland-substance were felt, especially in the lower and outer part of both breasts, but most distinctly in the right. Affected lymph nodes now appeared markedly in the right, slightly in the left axilla. Skin still normal. Nipples progressively retracting. Breasts movable still beneath the skin and upon the deeper tissues. In June tuberculous peritonitis originating in the uterine appendages appeared and suggested a tuberculous invasion of both breasts along with carcinoma. No other tubercular lesions nor other systemic symptoms were apparent. November 5, 1897, laparotomy was done with relief of the peritonitis, which was found to be well marked and general. Prompt recovery. Discharge late in January, 1898, much improved, with the breasts also for the third time softer. The patient returned in May, 1898, with both breasts of stony hardness, right larger, both nipples deeply retracted, impossible to evert or pull them out, axillary nodes much affected. The skin of the left organ appeared still normal but the right was invaded by very numerous small nodules, which the patient refused to have removed and examined pathologically. Without any tubercular lesions appearing elsewhere the peritonitis relapsed, requiring repeated aspirations. Death occurred September 10, 1898. The autopsy showed the extent and degree of the peritonitis; no pulmonary or other foci. The breasts were indurated and cystic. The cystic fluid inoculated tuberculosis into guinea-pigs. The skin was invaded by inflammatory and proliferative changes. The gland areas showed typical epithelioma. There was absence of tuberculous tissue anywhere in these organs. The axillary glands showed cancerous invasion. The diagnosis was finally bilateral cancer with deposits of tubercle bacilli accounting for the inoculation results, but of too recent occurrence to cause tubercles.

Importance of the Anterior Incision for Resection of the Hip.—According to Rochet (*Revue de Chirurgie*, April 10, 1900) of the posterior incisions Langenbeck's rectilinear and Ollier's angular are the best. Ollier has taught that the incision may occupy any part of the area included in a Y the vertical stem of which is applied to the external surface and posterior border of the femur and posterior ascending branch directed to the posterior superior spine, while the anterior upper arm points half-way between the anterior superior and the posterior superior spine of the ilium. Free exposure of the bone is gained by either of the above methods, but at the expense of several of the muscles of the region. In young subjects where the trochanter must be reached Ollier also uses an incision postero-externally to it, convex downward. With this the trochanter and all its muscle-attachments are laid bare. He does not condemn the anterior or antero-external method, recognizes its absence of damage to the muscles but claims it affords less perfect drainage than the posterior incisions. E. Vincent reports 52 cases in which the trochanteric exposure was resorted to with good results. Up to 1895 the author always followed the posterior avenues of treatment, but has since then made the anterior incisions with entirely good results. The technic is similar to that enunciated long since by Schede, differing slightly. The incision begins just below the anterior superior spine of the ilium on the antero-external aspect of the thigh, slightly internal to the prominence of the rectus femoris, descends vertically 3-5 inches, and exposes the muscles, which Schede separates bluntly, carrying the rectus and sartorius outward and the psoas-iliacus inward, but the author retracts the sartorius and psoas-iliacus inward and the tensor fasciæ latæ and rectus femoris sharply outward. The field thus produced shows the base of the neck more freely and a wound whose margins are not restricted by the sartorius whose oblique fibers fix the external lip in the

former procedure. For the further wide access to the capsule the psoas tendon must be boldly separated from it by blunt dissection with a curved sound. As the division advances the muscle may be more and more retracted inward. One does not meet with any nerves or vessels of importance. The capsule is then incised from without along the axis of the neck and dividing the cotyloid ligament facilitates the dislocation, which with the more or less altered head is easily accomplished by forcible extension, outward rotation and pushing upward. The ligamentum teres is then divided. If the neck is to be resected close to its base the capsule must be loosened everywhere to the margins of the trochanter. More space can be gained, as in cases of tuberculosis with much suppuration and of complete or partial ankylosis by making a short transverse outward division of the rectus for part of its width, beginning preferably at the lower end, occasionally at the middle of the primary incision. The vastus externus and internus compensate for this damage, while the buttock remains untouched, which in the posterior incisions is irretrievably injured. After the ablation of the head and neck the cavity is wide open for the investigation of all the hard and soft parts much better than in the posterior operations, except those situated behind and below the joint which in that method are openly in view. Nevertheless, the anterior incision gives sufficiently unrestricted exposure to render treatment easy. The conclusions reached are that the posterior method is the better in partial or absolute ankylosis, in extensive suppuration and widespread tuberculosis, by the larger exposure and more direct drainage. That the anterior incision is the better in young subjects for coxalgia, for separation of the head and in general in all cases because it does not injure the muscular support and action of the buttock, renders original replacement and subsequent maintenance of apposition of the bones more easy and efficacious, makes the renewal of dressings less trying for the patient and attendants, exposes the important part of the dressing less to infection from fecal matter, and, finally, when drainage may fail, small counteropenings posteriorly will suffice to obviate the difficulty.

Epicarin in Dermatology.—The fact that most antiparasitic remedies are too irritating for delicate skins has led C. G. Pfeiffenberger (*Klin. therap. Woch.*, May 13, 1900) to try epicarin with the best results. Epicarin is a derivative of the naphtol series and constitutes a reddish powder of slight acid odor which in the form of a seven-per-cent. ointment is especially indicated in scabies and prurigo of children. A marked phenomenon is the rapid disappearance of pruritus. After one or two inunctions the skin will become red and dry with a tendency toward cracking. To prevent this and to hasten desquamation, and at the same time to control the coexisting eczema, it is advisable to resort to diachylon ointment, followed on the next day by a warm bath, and returning to epicarin only when renewed pruritus appears. The duration of the treatment is usually less than nine days. In eczema pure and simple, epicarin does more harm than good.

Remarks on Diphtheria.—J. W. Jervey (*N. Y. Med. Jour.*, June 2, 1900) advances many useful opinions with reference to the diagnosis and management of diphtheria. The atypical forms he classifies according to Koplik as follows: (1) There may be no local manifestations of membrane, but a slight angina with croupy cough. These cases may, however, convey a severe disease to others. (2) There are cases in which the tonsils are covered by a pultaceous exudate, but no consistent membrane is present. (3) Cases may present a punctate form of membrane, isolated and usually on the surface of the tonsils. (4) Cases which begin and run their entire course as a simple follicular tonsillitis. (5) Heubner describes cases, usually secondary, in young persons the subjects of wasting diseases, such as rickets or tuberculosis. (6) A mild chronic type of diphtheria has been observed by the author, with or without an accompanying membrane which usually appears in the nose or nasopharynx. As the diagnosis is so difficult, or even impossible, in these atypical cases, a microscopic examination is almost imperative, not so much on account of the recovery of that particular patient as affording knowledge which may prevent the spread of disease. The author states that he believes that a diphtheria infection is added to about twenty per cent. of all scarlet-fever cases. He also says that the diagnosis of diphtheria is frequently made for the first time when certain post-diphtheritic lesions are recognized. An intimate connection between diphtheria and acute rheumatism is also suggested by the author who urges that both are specific infectious diseases, causing serious local disturbances by the formation of fibrinous exudates, and showing marked systemic toxemia. Diphtheria is most frequent in children from one to fifteen years of age, while rheumatism is most commonly seen from fifteen to forty.

Uterine Tuberculosis.—Three cases of this affection are described by Michaelis (*Beitr. z. Geburtsh. u Gynækol.*, 1900, Band 3, Heft 1). In the first a primary cervical focus had appeared The macroscopical diagnosis was a cancerous invasion of the lips of the os uteri. Total hysterectomy was done and no recurrence locally or generally had become evident after three and a half years. In the other two cases the tuberculosis was secondary to a polypus of the body in one case, and to a secondary cervical disease in the third patient. In all there was hyperplasia of the glandular and connective tissue, metaplasia of the epithelium and changes of the epithelium and stroma cells into an epithelioid type.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscripts should be typewritten.

SATURDAY, JUNE 9, 1900.

FIFTY-FIRST ANNUAL MEETING OF THE AMERICAN MEDICAL ASSOCIATION.

As might have been expected at this season of the year Atlantic City proved a very attractive place for medical men. The record registration, that of the annual session at Philadelphia three years ago, when 1994 members were present, was reached on the second day of the meeting. The number of medical men from the East was especially noticeable this year. New York sent a larger delegation than ever before. The awakening interest in the New York State and County Medical Association had had a very noticeable effect on New York interest in the National Association. It seems clear that the unfortunate division of medical society interests in New York which has kept the Empire State from exercising her due influence in National medical matters will soon be bridged over by the realization that a great National Association, both powerful and dignified, can accomplish almost incalculable good in the betterment of present medical conditions in this country.

Probably no presidential address to the Association in recent years has been listened to with such careful attention as was that of Dr. Keen, and none greeted with more enthusiastic marks of approval or more generous applause. The address appears in the present issue of the MEDICAL NEWS and deserves faithful perusal by all who were not at the meeting. In Dr. Keen's hands the old antivivisection question becomes almost new.

The questions of endowment for medical teaching and research received a dignified presentation that puts the matter clearly before the public. The comparative endowments of medical and theological schools show how much the existence of the private medical school in the past has hampered the cause of medical education. It suggests a vista of most encouraging possibilities now that medical schools have become in fact great public institutions.

A feature of these yearly meetings of the American Medical Association that is every year growing in significance is the sessions of auxiliary bodies of medical men representing special phases of professional life. The National Confederation of Medical Examining Boards, the Association of Medical Colleges, the American Academy of Medicine, the American Medical Editors' Association—all are serving the very commendable purpose of bringing men together who are engaged in similar lines of medical work. These annual reunions cannot fail to be of great service in broadening the views, while at the same time adding to the practical knowledge from the experience of colleagues. Standards of medical education are raised as a result of the association of educators seriously intent on training as well as attracting medical students. Members of State Examining Boards learn from each other the lesson of dealing with legislatures for the suppression of quackery by the successes and failures in States other than their own. The present condition of opinion among the members of the Confederation of Examiners seems to show that it will not be long before the privilege of interstate exchange of medical licenses and the fullest medical reciprocity will be a fact and not a dream. In a word, there lies hidden in the proceedings of these related organizations, neglected by the profession at large, unknown even to most of the members of the American Medical Association itself, the story of many a bit of progress that will in the near future contribute not a little to the amelioration of present evils in medicine.

The smallpox epidemic that is reported from various parts of the country occupied the atten-

tion of nearly a full session of the Section on Medicine. Officers of Health Boards from various States are strongly of the opinion that we are on the eve of a serious outbreak of smallpox in many parts of the country unless stringent precautions are taken to prevents its further spread. Meantime, there are experts in smallpox who insist that some of the epidemics now raging in the South are not true smallpox. Evidently there is opportunity for painstaking investigation that may settle disputed diagnosis and perhaps prove a distinct contribution to nosology.

Discussions on dysentery, yellow fever and rheumatic heart-complications were contributed to by authorities on these subjects. The question, is acute jail and work-house dysentery, as it occurs epidemically in this country, due to the bacillus isolated at Manila by Flexner, is suggested by Osler as well worth investigation. The bacillus icteroides is not unquestioningly accepted for yellow fever, although its cause was well advocated. All are agreed that for the prevention and amelioration of heart-complications in rheumatism absolute rest is the most essential part of the treatment.

The Atlantic City meeting has been the most successful of the American Medical Association to date. The social side of the meeting was most interestingly filled by the arrangements of the local committee and the features of it will long be remembered by the visitors. There was very little of medical politics in evidence this year and the ideal of a friendly meeting of brothers in medicine to discuss subjects of mutual interest was more perfectly fulfilled than ever before.

PERNICIOUS ANEMIA—FREQUENCY AND ETIOLOGY.

In our editorial on the recent Congress of American Physicians and Surgeons we called attention to the fact that pernicious anemia seems to be much more frequent everywhere, and especially in this country, than has been previously noted.

Until Biermer's article in 1871, none but isolated cases of the disease had been reported. Addison's marvelous discernment and power of synthesis enabled him years before to pick out certain fatally progressive cases of anemia as distinct nosological entities, but his observation attracted little attention and the disease he described was considered extremely rare. At the last meeting of the Association of American Physicians one hundred and fifty cases of pernicious anemia that have been seen by American medical men within the last ten years were discussed. Rarity, therefore, can scarcely be considered a distinctive note of the disease. Practitioners who are expert in blood-work and who are on the alert for pernicious anemia will doubtless henceforth see many more cases of the disease than have been reported in the past.

The cause of the disease remains almost as much a mystery as ever. Two recent contributions to its etiology are of special interest. It has been pointed out in Germany that toxic influences are often at work on the organism during long periods previous to the development of pernicious anemia. In several cases morphinism was a feature of the previous history; in others plumbism. Dr. Grawitz of Berlin has especially insisted on this toxic origin of pernicious anemia. He has seen it in workers in laundries where gas was used for heating purposes and the poisonous products of incomplete combustion were allowed to vitiate the air of the rooms, in which employees were crowded together for twelve to fourteen hours a day. He also insists on the toxins of tertiary syphilis and the sclerotic bone changes they induce, as important factors in the etiology of the intense blood dyscrasia.

Drs. Cabot of Boston and Billings of Chicago, who reported most of the cases at the recent meeting, are agreed that the absorption of toxins from the gastro-intestinal tract plays an important rôle in the etiology of the disease. Constipation has practically always existed for a good while before the development of the pernicious symptoms, and, as Dr. Cabot points out, the mild cases are those which have a tendency to diarrhea. When a corresponding idea with regard to the etiology of chlorosis was broached by Sir Andrew Clark, to the effect that intestinal autoinfection was a prominent factor in that disease, the notion was not at first received with any favor. We have learned to appreciate, however, how important the gastro-intestinal element is in the etiology of chlorotic anemia and doubtless will in time also ascribe to it its due influence in pernicious anemia.

Meantime, this suggestion as to the etiology of the disease seems about to bear fruit for the still more arid matter of the therapeutics of the disease. Mild purgation accomplishes more than any other form of treatment. Besides this hypodermatic injections of normal salt solution, given

on the theory of washing toxins out of the blood, have proved of some benefit. The only therapeutic agent of promise is arsenic. In some hands this has proved distinctly beneficial, but, unfortunately, in others it has failed to fulfil the expectations aroused by the claims of good observers.

ECHOES AND NEWS.

Testing Filters.—The Philadelphia Bureau of Health is making a test of water-filters with the object of placing them in the school buildings of the city.

Accident to a Physician.—Dr. Justin Herold of New York was badly hurt recently in a collision between a trolley car and a cross-town horse car. His leg was crushed. He was taken to the Presbyterian Hospital.

The Associated Physicians of Long Island.—The spring meeting of this Association will be held at Northport June 16th. The Northport Yacht Club and municipality will entertain the members of the organization.

Father Damien's Companion.—The Rev. Father L. L. Conrady, M.D., is in Philadelphia. He has spent eleven years among the Hawaiian lepers and was with Father Damien when he died. He has lately received the degree of M.D. and will work among the lepers in China.

Philadelphia Health Report.—Deaths for the week ending June 2d were 419, a decrease of 5 from those of last week and 7 from the corresponding week of last year. Contagious diseases: Diphtheria, 56 cases, 9 deaths; scarlet fever, 64 cases, 5 deaths; typhoid fever, 51 cases, 10 deaths. Influenza caused 2 deaths.

Honor Men at Columbia.—The following ten students were the highest in standing at the College of Physicians and Surgeons and are privileged to compete for the Harsen Prizes of $500, $300 and $200 respectively: Otto Mensel, H. G. Dorman, E. L. Beebe, A. W. Bingham, M. G. Seelig, T. J. Abbott, K. M. Vogel, A. W. Habschmitt, E. Moschcowitz, P. E. W. Menk.

The Pathological Institute.—On account of the space required in the present number for the report of the American Medical Association the publication of letters from Dr. Spitzka and Dr. Van Geison, in reply to the communications of Dr. Wise in regard to the Pathological Institute which appeared in the Medical News of June 2d, has necessarily been postponed until our next issue.

The Welsh Festschrift.—Following the Festschrift of Dr. A. Jacobi, we note with pleasure the "Contributions to the Science of Medicine," dedicated by his pupils to Prof. William H. Welsh of Johns Hopkins University on the twenty-fifth anniversary of his Doctorate. This is a magnificent quarto volume of 1066 pages, beautifully illustrated, issued from the Johns Hopkins Press. It contains some thirty-eight articles.

Quarantine Station Visited.—On June 2d Drs. Janeway, Bryant, Peabody, Polk, Biggs, Gardner, McLane, Derby, Draper and Prudden of the Medical Consulting Board of the Department of Health at Quarantine in New York Harbor, visited the boats and buildings of the Department, and also inspected Hoffman and Swinburne Islands. Dr. A. H. Doty was warmly complimented on the condition of the Quarantine Station.

Scientific Men to Meet in New York.—The fiftieth annual meeting and reception of the American Association for the Advancement of Science will be held at Columbia University, New York, during the week beginning June 23d. In this Association are included the fifteen largest scientific societies in America, and among them will be represented the American Chemical Society, the American Microscopical Society, the American Psychological Society and the American Physical Society. Governor Roosevelt will make the address of welcome.

Athletics Barred.—The College of Physicians and Surgeons of Chicago, after an animated debate, has decided henceforth to refuse recognition to athletics and no longer gives official sanction and support to the College football team which has taken so prominent a part in intercollegiate athletic competitions. This step has been taken because experience has taught the Faculty that College athletics have a demoralizing and disturbing influence on the students and interfere with the educational work of the College.

Cornell Commencement.—The second annual commencement of Cornell University Medical College was well attended last night at Carnegie Hall, New York City. Fifty-three graduates received their diplomas from Dr. J. G. Schurman, President of Cornell University. Of this number twenty-one were women gradutes, who in their mortar-boards and academic gowns made a pleasing appearance. Prof. Schurman announced that thirty-four of the graduates have already received appointments in hospitals in this and adjoining cities.

Death of Dr. Miller.—Dr. Truman W. Miller died May 31st at his residence in Chicago. An attack of grip was followed by blood-poisoning. He was President of the Chicago Polyclinic and Professor of Surgery in that institution. He was consulting surgeon to St. Joseph's and the Alexian Brothers' Hospitals; surgeon-in-chief to one or two railroads, and for many years was attending surgeon of the Cook County Hospital. Dr. Miller was born in Seneca County, N. Y., March 2, 1840. He took his first course of studies at Obart College, Geneva, N. Y., and com-

pleted his education at the College of Physicians and Surgeons, New York.

Faculty Changes.—At the annual election of the College of Physicians and Surgeons of Chicago, which preceded the discussion on athletics and other subjects, Dr. William E. Quine was elected Dean; Dr. D. A. K. Steele, the Actuary, and Dr. William Allen Pusey, Secretary. Dr. Louis J. Mitchell was appointed Professor of Anatomy; Dr. H. E. Santee, Professor of Anatomy; Dr. Frank X. Walls, Professor of Practice of Medicine; Dr. John L. Porter, Professor of Orthopedic Surgery; Dr. D. N. Eisendrath, Professor of Surgical Pathology; Dr. Joseph M. Patton, Professor of Physical Diagnosis. Dr. W. A. Evans has been retained as Professor of Pathology.

Public Health Matters.—There were 426 deaths reported to the Chicago Health Department during the last week, being 76 fewer than the preceding week, and 14 fewer than the corresponding week of 1899. All the principal causes of death show a reduction excepting bronchitis, consumption and heart-diseases. Consumption was the leading cause of mortality. There were 60 deaths recorded from this disease. Deaths from heart-diseases continue to be exceptionally high, 433 having been reported during the week from this cause. There were 11 deaths from measles and 7 from whooping-cough during the week. A reduction of 60 per cent. in deaths from the acute intestinal diseases is also reported, due largely to lower temperature prevailing.

Chicago's "Diploma Mill."—A Post-Office inspector invaded the Metropolitan Medical College on West Van Buren Street, Chicago, last Monday, and arrested four of its officers. At last report the president, vice-president and two secretaries were in prison awaiting the appearance of acceptable bondsmen. The institution is also known as the Independent Medical College and the National Law School, and the evidence shows that its faculty has been selling degrees for the practice of medicine and law at prices ranging from $3 to $200. The inspector who made the arrest says the fraud is one of the largest the postal authorities have ever had to deal with and that the "graduates" of the institution are practising in every State and even abroad.

The Psychology of Crowds.—Some of M. Le Bon's views, as set forth in his book on *"The Crowd"* are well exemplified by the following incident: A free dispensary in Chicago, said to be conducted in the interests of medical students, was attacked on May 31st by a crowd of infuriated Bohemians and Lithuanians. Stories of bodies being dissected in the dispensary had created terror among those ignorant people. On the above-mentioned date a boy disappeared. One of his companions at once reported that he had been waylaid and killed by the doctors. Within a few minutes afterward a mob of several hundred people were at work demolishing the building. They came upon the missing child lying quietly and as happy as his illness would permit him to be. Presently the police appeared and a number of arrests were made.

Obituary.—Dr. Joseph Davis Osborne, a well-known physician of Newark, New Jersey, died on June 2d in his sixty-seventh year. He was graduated from the College of Physicians and Surgeons. He served throughout the war as a surgeon in the Fourth New Jersey Volunteers.—Dr. E. O. Shakespeare, an eminent pathologist, died suddenly of heart-disease in Philadelphia June 1st. He was born in 1846 and graduated from the medical department of the University of Pennsylvania in 1869. He practised at Dover, Del., until 1875, since which time he has resided in Philadelphia. He served on the staff of the Philadelphia Hospital and was at various times president of local and national societies. In 1885 he was appointed by President Cleveland to report on cholera in Europe and India, his report being a most valuable one. He also made various other investigations regarding contagious diseases, studying with Koch in 1886. By Dr. Shakespeare's death Philadelphia loses one of its most tireless and brilliant physicians.

The Bubonic Plague.—Advices from various parts of the globe concerning the progress of the plague are not calculated to relieve the sense of danger which must possess the minds of all who have observed its course. Although Dr. George F. Shrady, during his recent visit to San Francisco in behalf of the *New York Herald,* was able to report that no case was then known to the local health board, he had scarcely left the city before bacteriologic investigation proved a suspicious death to have resulted from the disease. Ten thousand Chinese in that city are now using every means, both legal and indirect, to thwart the efforts of the sanitary officers. The Chinese minister at Washington has been appealed to by his countrymen in San Francisco for aid against what they consider unjust quarantine measures. Temporary accommodations for the segregation of three thousand Chinese upon Angel Island have been provided.—Sixty-one cases of plague are reported at Rio Janeiro in Brazil.—The Argentine authorities have taken advantage of the disappearance of the disease since May 11th to declare the Republic free from the plague; but at the same time they have decided to close the public schools lest it recur.—New cases and deaths are daily reported from Port Said.—India continues to reckon its victims by thousands, and China and Japan are constant sources of danger to our commerce.

The Medical Advertiser.—Interesting features of the recent meeting of the American Medical Association held at Atlantic City were the numerous booths of many of our prominent drug manufacturers, medical publishers, scientific and surgical instrument makers. These booths were very attractively gotten up and claimed much attention from the doctors.

CORRESPONDENCE.

OUR LONDON LETTER.

[From Our Special Correspondent.]

London, May 31, 1900.

CONFERENCE OF MEDICAL ASSOCIATION ON MEDICAL ORGANIZATION—REFORM OF THE GENERAL MEDICAL COUNCIL DEMANDED—DEPUTATION OF THE BRITISH MEDICAL ASSOCIATION TO THE GOVERNMENT ON THE MIDWIVES' BILL—THE CHAIR OF MEDICINE IN THE UNIVERSITY OF EDINBURGH—APPOINTMENT OF DR. JOHN WYLIE—DEATH OF GEORGE VINER ELLIS, THE ANATOMIST—THE CREMATION MOVEMENT IN ENGLAND—ERECTION OF THE FIRST MUNICIPAL CREMATORIUM—DEMOLITION OF INSANITARY HOUSES AND LEGAL QUIBBLES.

Delegates from over fifty medical associations have met at Manchester for a conference on medical organization. Mr. Victor Horsley in opening the meeting alluded to the impossibility of obtaining adequate discussion of the topics to be dealt with at the meetings of the British Medical Association. The General Medical Council is not as fully representative of the profession as it should be, considering the judicial power which it possesses over every member of the profession and its position as arbiter of medical education. The Council is a place of retreat for members of the profession who have practically given up work and have lost touch with the medical schools. Mr. Horsley advocated an annual registration fee for the medical profession similar to that paid by the lawyers, so that by means of larger funds the General Medical Council would be better able to carry on its work. With a strong financial position it would have greater influence on the Government, for the Government looks upon all bodies that approach it in a kind of materialistic way, and if it knows that a body is wealthy it considers that its stake in the country is greater! This argument is certainly a startling commentary by a member of the General Medical Council who ought to know something about the ways of the Government. If such a spirit of sordid materialism dominates the Government in medical legislation which intimately concerns the whole country, rich and poor alike; if in deciding what is for the benefit of the community at large they are to be influenced by the state of the banking-account of the General Medical Council, how will their actions be determined in other spheres where higher motives can have much less weight? Yet there are people who say that financial motives have nothing to do with the policy which brought about the South African War! A resolution that general practitioners should have a much larger representation on the General Medical Council was carried. Resolutions protesting against any legislation that will give a legal status to midwives as a class, in favor of raising the standard of preliminary education necessary for admission to the medical profession, that the right of receiving pupils be restored to general practitioners, and that the benefits of hospitals and medical charities should be limited to persons of limited means, were also carried.

In connection with the Midwives' Bill a deputation from the British Medical Association was received at the House of Commons by the Solicitor General with the object of explaining "the changes which were considered necessary in the public welfare." The deputation considered that the first defect in the Bill was that it contained no penalty for malpractice and that it would be most difficult to reach an offender. The Central Midwives' Board would consist of London men only who could not exercise sufficient control. The Board should be made representative of the different districts in the country. It ought to be made clear that the failure of a midwife to summon medical aid in cases of difficulty or danger was misconduct within the meaning of the Act.

Dr. John Wylie has been appointed to the Chair of Medicine in the University of Edinburgh rendered vacant by the death of Sir Thomas Grainger Stewart. He is fifty-six years of age. He began the study of medicine in the University and graduated with honors in 1865, being awarded a gold medal. He has held the posts of house-physician and house-surgeon in the Royal Infirmary. In 1870 he became a Fellow of the Royal College of Physicians and Lecturer on Pathology in the Extra-Academical School. In 1878 he was appointed Lecturer on the Practice of Physic. In 1876 he was made Assistant Physician to the Royal Infirmary, and in 1882 Physician. In addition to the teaching of medicine implied by these appointments Dr. Wylie has in connection with his work as an extra-academical lecturer conducted special supplementary summer courses on medical ophthalmology, laryngology, and electricity. When Professor Fraser went to India on the Plague Commission Dr. Wylie was requested to teach clinical medicine in the University in his stead and to take charge of his wards in the Royal Infirmary. His most important publication is a book on "The Disorders of Speech," which appeared in 1894. His reputation in Edinburgh as a diagnostician and clinical teacher has always been exceedingly high. His lectures and clinics are the most popular in the School. It is noteworthy that Dr. Wylie did not support his application for the Chair of Medicine by a single testimonial, but relied solely on his work and appointments.

The death of George Viner Ellis, F.R.C.S., the anatomist, recalls to the present generation of practitioners a name that was a household word in their student days. His book entitled "Demonstrations of Anatomy" was universally recognized as the standard of the most reliable works extant. He was born in 1812 at Ministerworth near Gloucester, and was apprenticed to a local medical man, but at the instigation of his uncle, Daniel Ellis, F.R.S., he was sent to University College which had been only recently founded. He became M.R.C.S. in 1835, and was elected

one of the original Fellows of the College of Surgeons in 1843. He was a very successful student and was appointed Demonstrator of Anatomy under Professor Richard Quain. In 1850 he succeeded him as Professor of Anatomy. Together with William Sharpey he co-edited the sixth edition of "Quain's Elements of Anatomy." In 1865, in conjunction with Mr. G. H. Ford, he published "Illustrations of Dissections"—a series of life-size colored plates which found a place on the walls of many dissecting-rooms. He devoted his life to the teaching of anatomy, and labored indefatigably. One of his peculiarities was that he would not allow smoking in the dissecting-room. On one occasion the students petitioned the Council for leave to purify the atmosphere with "the fragrant leaf." The permission was granted, but Ellis sent in his resignation and would not withdraw it until the permission was rescinded. His most important observation was the discovery of the corrugator ani muscle.

In a few weeks the Hull Corporation will have completed the erection of the first municipal crematorium in England. The Corporation determined eight years ago that in the public interest a crematorium was desirable, but, although preparations were at once begun, it has been found impossible to complete the work earlier. Many obstacles and prejudices had to be overcome. The example of Hull has stimulated other progressive cities. A large number of corporations, including Bournemouth, Cambridge, Exeter, the City of London, Sheffield, and Walsall, are seeking powers in Parliament to establish crematories, whilst other towns which have obtained powers are putting them into operation. The Hull Crematorium is a picturesque red-brick building with artificial stone dressing. The chapel is a spacious apartment, twenty-four feet square, and leads to the incinerating-chamber, which is surmounted by a seventy-foot tower forming a screen to the chimney. The interior of the cremating-chamber is quite invisible to the mourners. The coffin is placed upon a catafalque, and when the committal sentence is reached in the religious service it passes noiselessly by means of a hidden mechanism through curtains into an intermediate chamber. The curtains fall before the door of the cremating-chamber opens. The chamber is filled with an intensely oxidizing gas in a state of incandescence. The process occupies about an hour and there is no noise, smoke or flame. The ashes are placed by mechanical means in an urn, so that the remains are not handled in any way.

An extraordinary result of legal proceedings for the demolition of houses unfit for habitation in Southwark shows that the reputation of English law as the embodiment of common sense is not always well founded. When the case came before Quarter Sessions the counsel representing the owner argued ingeniously that as nobody lived in the houses they were not "dwelling-houses" within the meaning of the Act under which they were ordered to be abolished. The Court quite taken aback by this quibbling allowed the point to be remitted to a higher court which again sent the case back to the Quarter Sessions to determine how much of the premises was a danger to the public health. It was then alleged that that portion of the property had been demolished. Although the Vestry were not satisfied with the condition of the property, no order could be obtained and each side had to pay its costs.

SOCIETY PROCEEDINGS.

AMERICAN ACADEMY OF MEDICINE.

Twenty-fifth Annual Meeting, Held at Atlantic City, June 2 and 4, 1900.

FIRST DAY—JUNE 2D.

The meetings was called to order at 11 A.M. by the President, Dr. G. Hudson Makuen of Philadelphia. The Secretary, Dr. Charles McIntire, read the minutes of the Columbus meeting. The Treasurer reported that the Academy is free from debt, but that the balance on hand is not as large as usual. The year has been marked by several losses by death.

Among the Fellows elected to the Academy were Drs. O. A. Emberly of Massachusetts, Ella B. Everett of Philadelphia, Thomas Snyder of Niagara Falls, A. O. J. Kelley of Philadelphia, J. Addison Joy of Atlantic City, Judson Daland of Philadelphia and W. R. Powley of Atlantic City. Drs. Risley and Carhart were appointed Auditing Committee, and Drs. Connor of Detroit, Jackson of Denver and Wilson of Columbus were appointed on the Nominating Committee.

Principles Respecting Specialism and Advertising.—The Secretary read the report of this Committee, which first defines the word specialism, as used by the Committee and presents the following propositions: (1) Specialism is not only desirable; it is unavoidable. (2) It is proper for a physician to seek to perfect himself in the direction of his greatest ability, even to the neglect of some other field of practice. (3) A specialist as well as the general practitioner may have a practice directly with his patients, or indirectly through consultation. (4) In his direct practice, a specialist ought not to be an exclusivist. In his consulting practice, a specialist stands in a different relation to his fellow-physician than do general practitioners in consultation. He is rather a coadjutor than a consultant. (6) Specialism *per se* does not create discord in the harmony of professional intercourse. (7) The time to enter upon a specialty cannot be predetermined by rule.

As to advertising: (1) No physician can escape advertising. (2) The true physician serves humanity first, the earning a livelihood being secondary. (3) Any method of advertising reversing this order is not to be commended. (4) Any

method of advertising which only seeks to inform the public that the advertiser is ready to be of service is permissible. (5) The above principles are fixed, their application varies with the environment. (6) Regulations restricting advertising should be equal in their action.

The Medical Aspect of the Home.—A Symposium on this subject was then presented in several papers.

The Essentials for a Healthful Family Existence.—Dr. Rosa Engelmann of Chicago read a paper on this subject and stated that healthy family-life depends on health, character, intelligence, industry, frugality, mutual affection, forbearance and the wherewithal to furnish a happy and healthy environment. Of supreme importance for the development and maintenance of these attributes is the separate-housing system. Among the essential conditions mentioned are fresh air and sunshine, adequate pure water-supply and good plumbing, healthful employment, healthful recreation, educational facilities.

Early Training to Avoid Degeneracy.—Dr. J. Cheston Morris of Philadelphia furnished as a text an incident of a little girl pountingly disobedient and the necessity of an early training in submission to authority. Acts speak more effectively to children than mere exhortations or commands. Dr. Morris stated that the training of self-control must begin early in life and that the reign of law and the influence of patient example are necessary to bring them about. Heredity so-called is often but the unconscious imitation of the parents' peculiarities by the very young.

Medical Supervision of Children in Their Homes.—Dr. J. Madison Taylor of Philadelphia said that the child is supposed to be capable of satisfactory development if allowed moderately good opportunity and environment, and is seldom or never systematically directed in its physical growth or development. The consequence is that very many faults of both mind and body are acquired, many of which seriously disable the subsequent activity of the child. He stated also that no attention is paid to the mating of the parents, as is done in the case of domestic animals, and consequently many faults of inheritance or heredity show themselves. He showed that the province of the physician is limited as yet to the relief of actual illness and to repair the effects of disease. If only he were encouraged to direct the growing child his province as an apostle of preventive disease would enable him to accomplish infinitely better results than merely the repair of damage. The question of motherhood was discussed and the difficulties which arise from her lack of knowledge of those things which constitute a good mother. He stated that the first thing needed is that mothers should realize that the best specimens of human beings are not likely to come from haphazard up-bringing. He thought it safe to assume that skilled direction from a medical adviser will soon become recognized as of the greatest importance and that the children of the poor should be provided with opportunities for skilled physical direction. This could only be done by educating the public to realize the importance of this fact and by securing the cooperation of teachers of all grades in furthering such work.

School Hygiene and Medical Inspection of Schools.—Dr. W. M. Carhart of New York said that school-life should be harmonious with, and supplementary to, home-life. The growth of the child in bodily vigor, in strength of character and in intellectual attainments, should be as continuous at school as at home. School hygiene was divided into: (1) Hygiene relating to the personal habits of the child, necessity for cleanliness both of body and clothing. Avoidance of infection and exclusion of contagious cases. Physical basis of vice. Vicious habits to be discovered and corrected. (2) Hygiene in relation to methods of instruction. All children are not alike and should not be taught as if they were. Backward and dull children need special care. An inattentive child is usually defective in special senses and may be possibly slightly deaf. Weak eyes should also be borne in mind. (3) Hygiene in reference to the school environment. In this connection the writer said that school-buildings should be well located with adequate playgrounds, well furnished and built and with dry cellars. Good ventilation and clean rooms and lavatories with modern plumbing are also necessary. Desks and seats should be adjusted to the size of the children.

Defectives and Delinquents Inside and Outside the Family.—Dr. James W. Walk of Philadelphia gave the sociological definition of defectives and delinquents. The influence of defectives on other members of the family circle was considered, as was also the influence of aggregate life (in hospitals, asylums, etc.) on defectives. The influence also of family-life on defectives was spoken of. Delinquents and their environment were discussed in a similar manner. The author said that efforts to benefit defectives and delinquents should be consistent with the welfare of society in general.

Alcoholic Intoxicants and Home Sanitation.—Dr. J. W. Grosvenor of Buffalo considered the effect on moral character, intellectual development and physical integrity of its inmates. Two remedies of value for the relief of the unsanitary condition of the home were suggested, *viz.*, education and law. The writer considers that the enlightenment of the public along all sanitary lines is incumbent upon all boards of health. In the conservation of public health the medical profession has an important position. It is the opinion of the writer that the physician should not only by precept teach the danger of alcoholic intoxicants, but place himself and his home outside the use of alcoholic stimulants of every description. The clink of the inebriating cup should not be heard at his festive board.

The Hygiene of Vision in the Home.—Dr. S. D. Risley of Philadelphia made reference to the family living-room—its origin, pleasures and evils.

The natural and artificial lighting of the home were spoken of and the importance of sufficient and suitable illumination of the home in conserving the general health and vision of the family was emphasized.

Physician's Influence Regarding Vacation Schools.—Dr. Helen C. Putnam of Providence, R. I., said that inventions and municipalization have altered the popular minds that free schools were originally planned to supply and that to-day they should do more for citizenship, character-building and physical development. In the author's opinion liberally-educated medical specialists are needed in this readjustment. Reference was made to vacation schools started by philanthropists to protect from their environment the children living in the poorest wards, and developing into a permanent institution of direct influence upon educational systems. In these schools no books are used, pedagogic excursions into the country are made, manual training by wood and iron work is taught, esthetic development of music, color work, and outdoor sketching are encouraged, outdoor gymnastic games are indulged in and self-government in place of autocratic rule obtain.

Objects of Academy.—In his address to the Academy the President, Dr. G. Hudson Makuen, said that the American Academy of Medicine was instituted about a quarter of a century ago. Its chief object originally was to promote the higher education of medical men. Although it has been suggested that there appears to be no longer good reason for its continuance, never in the history of medicine, or in the history of the world, has there been so great a field for medico-sociologic investigation.

That the problem of the care and treatment of the so-called defective, delinquent, and dependent classes, has not been solved is shown by the authentic statement that these unfortunate classes are increasing in a proportion far greater than the increase of our population.

In precivilized times, only the fittest survived. Now we are endeavoring to establish a new law and our best efforts are being directed towards the survival of the unfit. We teach the lame to walk, the blind to see, the deaf to hear, and the dumb to speak.

Members of this Academy are formulating plans for a scientific process of selection. Its essential features may be surmised to be a revision in the immigration laws and the laws regulating the marriage contract. For those who respect not the law there has been suggested another remedy—that of asexualization. This with little doubt during the early part of the next century will become a legalized practice.

Our treatment of the degenerate classes has been inadequate and unscientific. Indiscriminate dispensary service is probably the most depraving and the most demoralizing of all the indiscriminate charities.

Pauperism, criminality, insanity are all one interdependent family, and if we would diminish one, we must attack all three. Following close upon the evils of indiscriminate charity are those of indiscriminate institutionalism. It is said that the city of Philadelphia supports at an enormous cost a benevolent institution for every 10,000 of its inhabitants.

In the treatment of criminals, institutionalism has a somewhat wider field, because criminals must be detained for a longer or shorter period of time; but there is much room for improvement in the character and conduct of these institutions also.

The hope of the future of our country is in the young, and if we would strike at the very root of crime, pauperism and mental deficiency we must improve our methods of education. The chief feature of the education in the Elmira Reformatory which produces marvelous results is manual training. Brain power, as Professor Christian of Yale University has demonstrated, may be developed by mere muscle training, independently of any special mental activity and if this be true it is reasonable to suppose that the highest cerebral development must come from a judicious combination of mental and muscle action.

Second Day—June 4th.

At the opening of the morning session the Nominating Committee announced the following nominations: President, Dr. S. D. Risley of Philadelphia; Vice-President, Dr. C. M. Culver of Albany, Dr. Rosa Engelmann of Chicago, Dr. G. G. Groff of San Juan, Dr. W. C. McClintock of Detroit; Treasurer and Secretary, Dr. Charles McIntire; Assistant Secretary, Dr. Alexander Craig of Columbia, Pa. The selection of time and place of meeting was placed in charge of the Council. The candidates were elected as read.

Dr. Grosvenor of Buffalo in referring to one of the papers on the parental teaching of children spoke of a custom of some parents in teaching their children to call the parents by their first names. He had observed this custom in his own city. He feared that if a strong protest were not made against it the custom would become more prevalent.

In the discussion of the paper of Dr. Engelmann of Chicago, Dr. Knopf of New York thought that while very desirable the separate-housing system seemed impracticable. He thought the solution of the problem could be more easily secured in the improvement of the tenements, the destruction of old tenements and the erection of new with new appliances of sanitation. In reference to the early training of children he suggested that the whole problem might be solved by adding to the higher schools for girls a chair of practical motherhood.

Dr. Connor of Detroit thought that the great underlying principle of the papers and discussion was an attempt to find out the weak methods in our art of training men.

Relation of the Academic to the Medical Course.—Dr. Howard S. Hansell of Philadelphia read

by title a paper on this subject, considering the topic under three heads: The State, the School, the Individual. The purpose of the paper was to advocate the admission of the college-bred man into the second year of the medical course.

The Opportunity of the Small Medical College.—Dr. Bayard Holmes of Chicago in this paper referred to the fact of the tendency toward large classes not being consistent with good pedagogy and to the small class and individual supervision being possible in the small school. As requisites were mentioned: A few teachers and leaders of men, with time and adequate salary; suitable buildings and laboratory equipment; a small hospital under the complete control of the college; a well-selected working library, containing the material for the study of medicine; intimate relations between the various departments; a curriculum granting freedom to teacher and student. All of these requisites, it was stated, are possible to the small college.

Neglected Clinical Opportunities.—Dr. S. A. Knopf of New York read a paper on this subject and endeavored to show that in spite of the vast progress many of our medical colleges have made during the past year toward a more thorough curriculum, our clinical teaching is still very deficient, not from any lack of clinical opportunities, but from the neglect to utilize those available. The writer contended that the essentials for a college graduate leaving college feeling that his clinical teaching, if not quite equal to that of any hospital graduate, is at least nearly so, were: (1) A cooperation of all the medical colleges located in one medical center for the purpose of a general and equal utilization of all the clinical material of their city. (2) The appointment of every physician and surgeon attached to a subsidized hospital as a clinical teacher independent of college affiliation, and the payment of a reasonable fee to these clinical teachers for their services rendered as teachers to the students. (3) The suppression of all didactic lectures for second-, third- and fourth-year students during the morning hours. (4) The obligatory presence of every second-, third- and fourth-year student in his capacity as senior or junior interne at the clinic or at the daily hospital visit of his teacher. (5) The keeping by the clinical teacher of a record of attendance and work, to be counted in the final examinations.

Experiences of a Volunteer Surgeon in the Philippines.—Dr. H. P. Ritchie, late Captain and Assistant Surgeon, 13th Regiment, Minnesota Volunteers, St. Paul, said with reference to the transport service that the causes of complaint and discomfort during the first expeditions were unnecessary as shown by the pleasant experiences of the home voyage eighteen months afterward. The effect of the campaign before Manila upon the future health of the troops was considered. The condition of Manila at the time of its occupation and its transformation under American rule was described. The climate was discussed, and the diseases among the troops briefly considered, with their prophylaxis and their danger to the civilian. The paper closed with a plea for instruction in tropical diseases.

"Good Form" in Professional Cards.—Dr. Charles McIntire of Easton in this paper referred to the source of gratification to the Fellows of the Academy of Medicine that there had been almost no necessity to discuss the individual actions of its members. Last year an exception was taken to the wording of a professional card, and the secretary was instructed to correspond with the member whose card was criticised. The present paper was the result of that correspondence classifying a number of professional cards from various parts of the United States.

Medical Editor for the Daily Journals.—As an argument for this need, Dr. Pyle called attention to an article recently appearing in the New York Herald entitled "Sleep-Cure for Nervous Diseases." This cure consisted of "eight grams of *bromine* every two hours in a glass half-full of water." It was further stated in this issue that the discoverer of this rest-cure maintains that rest—absolute, prolonged rest—is the one thing which persons suffering from nervous disorders stand most in need of, and that they can obtain the rest through the agency of 'bromine' better than in any other way."

The Mission and Duties of a True Physician.—Dr. C. F. Ulrich of Wheeling, West Virginia, in this paper said that only he could be regarded as a true physician in the strictest interpretation of the word who is endowed with the peculiar talents necessary for the work belonging to that noble and laborious vocation; who has acquired the high order of general and special education essential to successful work; who never relaxes his efforts to gain more knowledge in his profession as his horizon extends and as new discoveries are made. The true physician should perform the part of an educator by instructing his clients in maintaining good health.

Psychology as Preliminary to Medical Education.—Dr. W. J. Herdman of Ann Arbor, Michigan, said that normal anatomy and histology are essential to a right understanding of normal physiology. Psychophysiology must be known if we would correctly interpret psychopathology and create a rational psychotherapy. The author considered that at the present day a very small per cent. of candidates for the degree of doctor of medicine have pursued a systematic study of physiological psychology. Such knowledge was claimed to be essential to a right understanding and direction of educational methods since faulty methods of education result in disease. Functional disorders would be much better understood and more rationally treated were the physician well trained in psychophysiology. The mental element of disease is largely ignored by the practitioner of to-day, and in this soil left uncultivated by the scientific physician faith cures and other noxious weeds take root and flourish. The writer believes a broader preparation is needed to fit the physician to take possession of this field.

NATIONAL CONFEDERATION OF STATE MEDICAL EXAMINING AND LICENSING BOARDS.

Tenth Annual Meeting, Held at Atlantic City, June 4, 1900.

The meeting was called to order by the President, Dr. J. N. McCormack of Bowling Green, Ky.

The work of public interest of this session was the discussion of the subjects of the feasibility of uniformity in medical education and of interstate reciprocity in the granting and registering of licenses.

Cooperation of Medical Profession.—Dr. Emil Amberg of Detroit brought out forcibly the idea that if all the members of the medical profession of the United States or even a majority of them should unite in demanding reciprocity it would be granted. For true reciprocity it would be necessary to demand more uniformity in medical training. This can only be accomplished by a reduction of the number of medical schools and the elimination of the unsuitable ones. Private medical schools are in Dr. Amberg's eyes always a mistake and medical education should be under the care of the Government. Far from opposing improvements in medical laws, the lay press of the country can be depended on to second them if they are but once convinced of their real utility for the general public. This was the experience in Michigan when, in the absence of any law for the regulation of medical practice, the lay press took up the battle of the regular practitioners for the protection of the people from quacks. We are just entering upon the hygienic century. America will only take her proper place in the great advance in medicine that is about to come if her practitioners really possess the merit they are supposed to have.

Reciprocity and Medical Uniformity.—Dr. Spurgeon of Indiana offered a resolution providing for a committee that would suggest ways and means for the establishment of interstate reciprocity in licensure for the practice of medicine and for uniformity in medical education.

In discussing the resolution Dr. Wm. Warren Potter of Buffalo said that the present body is the only one of the many organizations meeting at Atlantic City at this time the members of which were officially recognized by State Governments. It was important not to derogate from their official positions. The question of advising legislatures as to reciprocity laws should come last. Uniformity in medical education is at present the desideratum. If this is obtained, then reciprocity will follow naturally. Uniformity in medical education can be advanced by the Confederation of Examining Boards and that of the medical colleges working together. Conference is needed, not hasty action. The motto must be *"festina lente."*

Dr. Egan of Chicago said that it was useless to hope for uniformity in legislation. It is impossible to convince legislatures of the crying needs of their own State. A law for the regulation of medical practice comes back from the legislature so mutilated as to be unrecognizable. Under existing laws much can be done toward remedying the present situation. The Illinois Board of Health has passed a resolution to accept the licenses of other States that comply with their regulations. The Attorney-General says the Board has not gone beyond its powers in so doing. Other State boards can follow the example. The courts can be depended on to favor public utility in the interpretation of the law and reciprocity is distinctly of this character.

Dr. Harvey of Massachusetts said that it is useless to hope that any committee under the sun can influence legislatures to give up their individuality. States will not accept the standards of other States. There is often no reciprocity even in the public schools of different cities of the same State. It is a chimera to look for reciprocity. Uniformity in medical education should be the watchword.

Dr. McCormack said that in all this talk of reciprocity he was reminded of a country-inn with screens to keep out flies which really kept them in. Many States seemed willing to have reciprocity so as to get rid of their surplus medical men. Each State should keep down quackery by stringent laws. What is needed most now is a committee that will report and weed out paper colleges. Information as to the status of such colleges would be most welcome to medical examining boards and be very helpful.

The Committee on Reciprocity was appointed.

The officers of the National Confederation of State Medical Examining and Licensing Boards for the ensuing year are as follows: President, J. N. McCormack, Bowling Green, Ky.; vice-presidents, N. R. Coleman, Columbus, O., and J. W. Egan, Springfield, Mass.; secretary and treasurer, A. Walter Suiter, Herkimer, N. Y. The Executive Council remains unchanged.

AMERICAN MEDICAL EDITORS' ASSOCIATION.

Annual Meeting, Held at Atlantic City, N. J., June 4, 1900.

The Association meeting was held during its annual banquet. The President, Dr. I. N. Love of St. Louis acted as toastmaster. The medical editors were welcomed by the Hon. Franklin P. Stoy, Mayor of Atlantic City, and by John F. Hall, Editor of the *Atlantic City Daily Union*. Among the other speakers who responded to toasts were Dr. Alonzo Garcelon of Portland, Maine, the oldest living member of the American Medical Association and one of its ex-presidents, Dr. Joseph M. Mathews of Louisville, a recent ex-president of the Association, Dr. Nicholas Senn of Chicago, Dr. J. V. Shoemaker of Philadelphia, Dr. W. C. Wile of Danbury, Ct., the *Danbury Medical News* man, Dr. Chas. H.

Hughes of St. Louis, Dr. Philip Marvel of Atlantic City, the Chairman of the Committee of Arrangements for this meeting, Dr. J. S. Stone of St. Paul, recently elected president of the National Association of Military Surgeons, and others. The meeting was most successful. One hundred and fifty guests sat down to the banquet which was prolonged until after 12 o'clock amid the pleasant reminiscences of the older members and the witty scintillations of their younger associates.

AMERICAN MEDICAL ASSOCIATION.

Fifty-first Annual Meeting, Held at Atlantic City, N. J., June 5-8, 1900.

[Specially reported for the MEDICAL NEWS.]

GENERAL SESSION.

FIRST DAY—JUNE 5TH.

THE proceedings were opened by prayer by the Rev. Frederick J. Stanley of Atlantic City.

A delegation of medical men from Columbus, Ohio, then presented a gavel for the use of the President of the Association at this meeting. The gavel is made of the wood of a tree from the family home of President McKinley at Canton, Ohio.

An address of welcome was delivered by Acting Governor Johnson of New Jersey. He said that the Governor is literally "half-seas over" at the command of his physician. There is only one man in New Jersey above the Governor, and that is his family physician who sent him abroad. Otherwise he would be here to extend the hearty welcome of the State of New Jersey to the American Medical Association. As it is, New Jersey in her Governor's absence receives her medical guests with heartiest greeting.

The Acting Governor recalled the fact that the first medical society in this country was organized in New Jersey. It first met in 1766 and its minutes are still in the possession of the New Jersey State Medical Society. New Jersey would be found on the present occasion to fully justify her past reputation as a cordial host for the unselfish profession which in this century have done so much for humanity.

The Hon. Franklin P. Stoy, Mayor of Atlantic City, extended the freedom of the city to the medical visitors. He promised that if any of the doctors should get into trouble the Mayor of Atlantic City would be in trouble with them. Meantime he bade them welcome and again welcome.

It was announced that a loving cup would be presented to Dr. Abraham Jacobi of New York by the Pediatric Section at their banquet on Tuesday evening, also that a public reception to him would be given at the St. Charles Hotel at five o'clock on the same day.

Dr. L. Duncan Bulkley of New York in the report of the General Business Committee said that during the past four years 2400 papers have been read before the Sections of the American Medical Association. This number is evidently beyond all reason. Some method of lessening the quantity must be devised. Meantime members are requested to present only papers that afford evidence of some real advance in medicine.

The President's Address was then delivered by Dr. W. W. Keen. It will be found elsewhere in the MEDICAL NEWS of this week.

The Treasurer's report was then read. During the year $38,965 has been received, $15,593 more than five years ago. Of this there is cash on hand $13,556. There is $3000 invested in the Indianapolis Loan and $10,000 in United States Government War bonds. Total amount of funds on hand $27,368.86. The Association is increasing not only in numbers but in the sense of responsibility of their duties. While but $1500 in dues was received during the first two months of 1890, over $15,000 was received during a corresponding time this year.

Dr. George H. Simmons, Secretary of the Association, then read his annual report. The Secretary then announced that the Third Pan-American Medical Congress will meet this year at Havana, Cuba, on Dec. 26th-29th. The American Medical Association has been requested to send delegates to this meeting. The Secretary reminded the members of the Association that the Pan-American Medical Congress owes its origin to their Association and they should take an interest in it.

Applications for membership in the American Medical Association have been received from Cuba, Porto Rico, the Philippines and from sixteen members of the Honolulu Medical Society. The Secretary suggested that the By-Laws of the American Medical Association be altered so as to admit these applying physicians.

A motion was then made that one delegate and one alternate from each State and Territory in the United States be appointed to attend the third meeting of the Pan-American Medical Congress at Havana, Cuba, in December, 1900.

A motion was then made that the Treasurer's and Secretary's reports hereafter be printed before the first general meeting and that they be circulated among the members of the Association for comment.

SECOND DAY—JUNE 6TH.

After the reading of the minutes of the first day's meeting the Oration on Surgery was delivered by W. L. Rodman, M.D., of Philadelphia. (See page 903 of this week's issue of the MEDICAL NEWS.) This was followed by the Oration on State Medicine by Victor C. Vaughan, M.D., of Ann Arbor, Michigan. (See page 907.)

The Business Committee recommended that the title of the Section on State Medicine be changed

to Section on Sanitation and Hygiene. This was approved. The committee recommended that the Committee on the Rush Monument Fund be continued. The Report of the Board of Trustees showed the receipts for the year ending December 31, 1899, including cash in treasury of about $20,000.00, were $109,115.33, the largest receipts in the history of the Association. The *Journal* expenses, plus the treasurer's expenses, amount to $93,669.40. Total cash on hand $14,355.51 and permanent investment in Government bonds and Indianapolis loan $13,812.50, or an aggregate balance on hand of $28,168.01. The average weekly number of copies of the *Journal* issued during the past year was 13,672. The trustees have decided to exclude from the advertising pages of the *Journal* all proprietary medicines advertised in the public press.

Dr. Geo. M. Gould presented the report of the Committee on Prize Essay. There were six competitors. The Committee was unanimous in awarding the prize to Dr. A. L. Benedict of Buffalo, New York. The prize is a gold medal about the size of a twenty-dollar gold piece, but twice as thick. Upon the reverse is a scroll supported by the emblem of Esculapius bearing the inscription "Awarded to A. L. Benedict, A.M., M.D., for Essay entitled 'Quantitative Tests for Proteolysis,' June, 1900." This is surrounded by raised letters, "Am. Med. Association Prize Essay." The obverse presents the usual eagle and shield—the National coat-of-arms. This is the first time that an essay has been considered worthy of the prize. The Committee recommended that hereafter the successful competitor be allowed to choose whether he will receive the medal or accept a bronze replica and the balance of the fund, $100.00, in money.

Dr. Rodman presented the report of the Committee on the Senn Medal, awarding it to Dr. F. Gregory Connell of Chicago for an essay entitled "Exstrophy of the Bladder."

The Committee on the Rush Monument Fund reported that the total of the fund at present amounts to $11,330.05. On motion the Committee was enlarged by three additional members.

Third Day—June 7th.

The Oration on Medicine was delivered by John A. Witherspoon, M.D., of Nashville, Tenn. A full abstract of the oration will appear in our columns next week.

The special Committee on Revision of the Constitution and By-laws, which had been enlarged by the addition to it of the General Business Committee and the Board of Trustees, recommended that the clause permitting members by invitation be amended so that it applies only to distinguished foreigners and men of special note; that the time allotted to the orations be limited to forty minutes each and that the time-limit of discussions of papers before the Sections be five minutes for each man.

The Nominating Committee presented the following officers for the ensuing year: President, Dr. C. A. L. Reed of Ohio; first vice-president, Dr. A. W. Calhoun of Georgia; second vice-president, Col. Woodhull, U. S. A.; third vice-president, Dr. Philip Marvel of New Jersey; fourth vice-president, Dr. W. E. Quine of Illinois; treasurer, Dr. H. P. Newman of Chicago; secretary, Dr. G. H. Simmons of Chicago.

The following men were chosen to deliver the orations: Medicine, Dr. N. S. Davis, Jr., of Chicago; Surgery, Dr. John A. Wyeth of New York; State Medicine, Dr. Geo. M. Rober of Washington.

Four trustees were chosen: Drs. W. F. Porter, E. F. Ingalls, Rodman and Matthews.

St. Paul was selected as the place of meeting in 1901.

An amendment to the Constitution was passed which provides that after nineteen hundred and one, no graduate of a college course with less than three years of regular instruction in the various branches of medicine can be considered as eligible to membership in the Association.

Section on Practice of Medicine.

First Day—June 5th.

Proposed New Section.—In his opening address Dr. Dock, Chairman of the Section, mentioned the fact that it is proposed to relieve the pressure of papers demanding presentation before the Section on Medicine by establishing a Section on Pathology. This would, however, emasculate the Section on Medicine by depriving it of the papers that had most scientific value. There is a strong feeling that for the accomplishment of really valuable work, the clinician should keep closely in touch with the pathologist. The present year's attempt to have an informal demonstration of pathological specimens promises to be most successful and instructive—a very valuable feature of the annual meeting. Arrangements should always be made, however, to supply the material from the country immediately around the place of meeting. This will save expense and the danger of the loss of valuable specimens in transit.

The Century's Clinical Work.—Life without self-examination is sure to be a failure, Socrates said; and our medical life will share this fate if we do not pause to pass it in review, to realize its failures and appreciate its tendencies. The end of the century seems an especially favorable moment to do this. In the first decade Corvisart recalled Auenbrugger's work and gave percussion a place in general medical diagnosis. Laennec in the second decade invented the stethoscope. For a time these methods did not spread. Then for a while overconfidence in them became the rule and now, as the result of confidence in other diagnostic methods, they are too often neglected. It is not so much that they are not known as it is that they are entirely omitted. In a recent case in which there was a transposition

of all the organs, the patient said he had been examined seven times for life insurance, and had been treated in a prominent hospital for pleurisy, yet the transposition of viscera had never been called to his attention.

Bright and Henle.—In the third decade of the century Bright showed the diagnostic significance of albumin in the urine and separated Bright's disease from other affections. In the fourth decade Henle showed the significance of tube-casts. The value of these tests has often been exaggerated, but the trouble too often in our day is that they are not used at all. The difficulty in the past has been that there were too many medical schools and that too much energy had to be expended in securing students rather than in training them. Fortunately, there is every reason to hope now that this condition of affairs is about to end. The improvement in medical education in this country toward the end of the century is most marked.

Instrumental Diagnosis.—Some of the newer methods of diagnosis, involving the use of apparatus, have fallen into ill-repute because too much dependence has been placed on them. None of the instrumental methods of diagnosis are capable of replacing entirely the old clinical methods. None of them will ever make up for the diagnostic skill to be gained only by experience at the bedside. Sometimes the instrumental diagnosis is committed to incapable hands, thus giving false ideas as to its value. The microscopic or bacteriologic expert should be chosen with as much care as an operator.

Medical Abuses.—Two of these are to be noted. Irregular practitioners are taking advantage of suggestive methods of treating disease which the profession should not entirely neglect. The success of such methods should show the regular profession their duty in the matter of suggestion as a valuable therapeutic agent. The manufacturing specialists occupy too much of the field of medicine. One large remedy manufacturer employs thirty clerks who do nothing but answer letters from doctors as to the treatment of disease. They know absolutely nothing of medicine nor do they pretend to know anything. They answer the questions proposed from the trade circulars of the manufacturer. This is just as it should not be. There is money in supplying the doctor with ready-made prescriptions and the work will go on until the physicians realize that their mistake will come back on themselves. The manufacturer is but a natural manifestation under the circumstances. "They come like water and like wind they go."

Biologic Examinations.—Dr. George M. Gould of Philadelphia bewailed the lack of biologic examinations of human beings. A few measurements are made in the athletic departments of universities, some physical examinations of school-children are made, careful examinations of recruits are instituted, and some psychophysical data gathered in the laboratories of physiological psychology, but that is all that is being done for the important science of living anthropology. Dr. Gould suggests that careful examinations should be made at intervals and then compared with each other so as to note the deterioration when it begins to occur. The dental is the only branch of the medical profession which has succeeded in convincing its *clientèle* that periodical examinations should be made whether symptoms exist or not. If this is advisable for so limited a sphere as the teeth, how much more so for important organs like the kidneys, the heart, the eyes and the ears! These organs do not give symptoms at the beginning of an affection but only when it has advanced, often to a hopeless stage. How often is hopeless kidney- or heart-disease discovered at some chance examination! Mental and nervous diseases are, as a rule, discovered too late for therapeutics to be of any use. Preliminary symptoms are utterly neglected. Periodical medical examinations would remedy this evil. The data of such examinations would be precious material for a comparative study of men. This would work a revolution in anthropology.

Specialists and Generalists.—The establishment of the custom of such examinations would restore the general practitioner to his dignity and position. As it is, the specialists are encroaching so much upon the territory of the general practitioner that he has really the narrowest specialty of all. He is coming to be scarcely more than a passer-on of patients to others, and, unfortunately, ethics will not allow the specialist to divide the fee with him.

Unless he is endowed with permanent anorexia and lives in a climate where clothes and houses are not needed, the poor general practitioner will be in a sorry plight. Perhaps it is providential that our new possessions, the West Indies and Philippines, are wonderfully favored by nature. If the conviction of the necessity for avoiding disease while in health, not merely looking for cure when diseased, has gained ground, the care of the health would once more be entrusted to the family doctor and he would occupy his old place of honor.

In the discussion Dr. Stockton of Buffalo said that the data suggested by Dr. Gould would be eminently applicable to the problem of heredity. If comparative anthropometric measurements and the records of physical examinations and pathologic conditions could be filed away, we would at the end of the next one thousand years know something definite concerning the questions of heredity. As it is our advance along this line is most problematic

The Hospital Clinical Laboratory.—Dr. C. N. Camac of New York said that the hospital and ward clinical laboratories are of so much service to the clinician as to be practically indispensable. Wherever introduced they have proved their usefulness. Certain objections to them are unfounded. It is said they occupy too much room, but all that is necessary is a space six by eight feet and a window. The essentials are really a

window and a table. It is said they are dirty, but a glass-covered table can be easily cleaned and the objection falls. Reagents that are poisons may fall into the hands of patients, but if this danger is really feared, they may be kept under lock and key. Residents, it is said, will appropriate its apparatus for their own use. This can be avoided by knowing, before appointments as residents are made, the character of the young physicians. The matter of expense is by no means as forbidding as is claimed. The original installation will cost in proportion to the quality of the microscope that must be purchased, but $200 will suffice for everything and that, too, of good quality. The maintenance is not expensive; $50 a year will be ample and $30 a year has been known to prove sufficient.

Blood-Examinations.—Dr. M. Howard Fussell of Philadelphia said that the examination of the blood gives such valuable information that it should not be neglected. He gave some examples of its value from his recent practice. In the case of a child taken with a sudden chill there was a remission and then after twenty-four hours another chill. This was repeated. The blood-examination showed that no plasmodia were present. The absence of the malarial parasite directed attention to the lungs where on the fourth day an apical pneumonia developed. In our day malaria should never be diagnosed unless the plasmodium has been found. The abuse of the diagnosis malaria for intermittent or remittent temperatures is now absolutely unjustified. For the diagnosis of the anemias blood-examination is most important. Not long ago a case of weakness and pallor, with loss of weight, in a physician led to the diagnosis of tuberculosis. The doctor himself, because of an enlarged spleen and some febrile temperature, diagnosed malaria. A blood-count showed the presence of 175,000 leucocytes. The case was one of leucemia. Recently a case diagnosed as cancer presented itself at the dispensary. Blood-examination showed that it was really a case of pernicious anemia. The use of Widal's test solves many of the problems, heretofore most knotty, which are prone to gather round the diagnosis of typhoid fever. Thousands of cases would doubtless have been saved during the late war by appropriate treatment, if the contract medical surgeons had used this important diagnostic method. Where leucocytosis exists typhoid is not present. In a recent case the patient had typhoid four years ago. The occurrence of fever led to the application of the Widal test which was positive. There were 20,000 leucocytes present, however, and the infection proved to be tuberculous. Dr. Fussell does not mention staining methods, because they require special skill and paraphernalia. Blood-counting, however, may be done very simply. The apparatus may be carried in a bag. If the blood be properly diluted when fresh and then kept in a tube closed by rubber caps, it is unnecessary to bring a microscope to the bedside. Dr. Fussell exhibited the bag in which he carried his instruments. It is about the size of the ordinary physician's "grip."

In the discussion Dr. Osler said that the ward clinical laboratories spoken of by Dr. Camac have now become a necessity. It is extremely interesting to have brought out how little is needed for their equipments. One item of the equipment that Dr. Camac did not mention is very essential —a good supply of cortical substance properly trained. As to Dr. Fussell's bag, it is a model for the general practitioner of the country. It is into the hands of a man who carries a bag like this and has the brains to use it that Dr. Osler would rather fall, if he were ill, than into the hands of many a pretentious theorist.

Etiology of Dysentery.—Dr. Simon Flexner of Philadelphia gave some details of his experiences in the Philippines when detailed by the United States Government for the study of dysentery. Two classes of cases were readily distinguished clinically—the very acute and the chronic. We are accustomed to think of all dysentery in the tropics as an entity, tropical dysentery, with which the amœba coli is associated etiologically in our minds. In the acute cases no amœbæ coli could be found. A bacillus was found very constantly, however, which resembles the bacillus coli communis not a little, but can be differentiated from it with certainty. This bacillus has also been found in Japan where a terrible epidemic of dysentery is raging. When the blood of a patient suffering from an acute dysentery is added to a culture of this bacillus, agglutination occurs. This has led to the attempt to make a serum for the disease. Animals can by the use of this serum be protected from doses of the bacilli that would ordinarily prove fatal to them. The serum has been used with reported good results on human beings in Japan. Since his return from Manila Dr. Flexner has seen a case of dysentery in which this bacillus was found. It occurred in a soldier returned from Porto Rico. At the autopsy the characteristic lesions of this form of dysentery were found. The ulcerations were superficial, not the deep erosions that occur when the disease is the amœbic form of dysentery. The bacilli had wandered into the mesenteric glands but not farther. There were no abscesses, such as occur so frequently in amœbic dysentery.

Chronic Dysentery.—A number of cases of chronic dysentery were observed at Manila, but the bacillus of acute dysentery was not found in the stools. A certain number of these began as acute dysentery and had the characteristic bacillus. Afterward they passed into the chronic form, the bacillus gradually disappearing. At first Dr. Flexner was under the impression that the rôle of the amœba in tropical dysentery had been very much overdrawn and that perhaps it did not stand in a causal relation to the disease at all. Further investigation, however, seems to show that the amœba does play an important rôle in the etiology of the chronic forms of dysentery.

Prospects of Immunity and Cure.—Dr. Flexner thinks that there is good reason to hope that the

disease can be much benefited by the serum that is prepared after the inoculation of animals with ascending doses of pure cultures.

In reply to a question of Dr. Osler, he said that it is not improbable that the epidemics of acute dysentery which occur in jails, work-houses, and asylums are due to this bacillus. Every epidemic of acute dysentery deserves to be investigated from this point of view. For thorough investigation cultures of the bacillus for comparative study are needed. Besides, the agglutinative test forms the very best diagnostic method. Dr. Flexner is ready to furnish cultures for these purposes to those who apply for them.

In reply to a question of Dr. Bridges as to the possibility of the coincidence of typhoid and dysentery, Dr. Flexner said that the two diseases may occur together. The agglutinative reactions of the two diseases are very distinct, however, and make the differential diagnosis very easy and assured.

Acute Tropical Dysentery.—Dr. Musser described a fatal case of dysentery in a soldier from Porto Rico in whom the characteristic agglutinative reaction described by Dr. Flexner occurred. He was thirty-two years of age, and had been fifteen months in Porto Rico, eight months of the time ill. He was extremely prostrated and very emaciated. There was marked pigmentation all over the body, not regular, however, but much darker in some parts. He suffered from boils, but cultures made from them were negative. He had the scaphoid abdomen of exhausted states. He passed no fresh blood and but very little mucus. Purpura was present and his gums presented all the characteristic appearances of scurvy. Only for the agglutinative reaction in his blood his condition would surely have been set down as scorbutic. There was no periodicity, no fever, but a tendency to subnormal temperature and steady progression downward. The post-mortem showed only superficial ulceration of the intestines and absolutely no multiple abscesses, although, as may be well understood, they were looked for very carefully.

In the discussion Dr. Osler said that the amœba, while it has lost its prestige as the sole cause of tropical dysentery, still retains its character as a causal factor in dysentery even here at home. In six cases of amœbic dysentery that have come under his observation during the past year, not a single one gave the agglutinative reaction with pure cultures of the bacillus described by Flexner. There exists, then, a form of dysentery distinct from the acute type of the disease.

In closing the discussion Dr. Flexner said, in answer to a question from Dr. Vaughan, that while the bacillus coli communis sometimes causes intestinal disturbance, it probably never takes on a virulence that makes it the active agent of a serious epidemic.

Serumtherapy of Pneumonia.—Dr. J. C. Wilson of Philadelphia has used a pneumococcic serum prepared by Dr. MacFarland of Philadelphia for the treatment of pneumonia. In 18 cases at the German Hospital in which it was used 4 were fatal. During the same time 20 cases were under treatment at the Pennsylvania Hospital without serum with 4 deaths. In the serum-treated cases all the other remedies usually employed were administered. Ice-bags, stimulants, *etc.*, were used as needed. Dr. Wilson thinks that the serum does good in relieving the symptoms, although it does not seem to shorten the duration of the disease, nor cause anticipation of the crisis.

Dr. A. O. J. Kelly of Philadelphia described an alcoholic case of double pneumonia in which the serum was used without effect.

Dr. Rochester of Buffalo said that large quantities of serum should be used. At first in diphtheria quantities entirely too small were employed.

Dr. MacFarland described the production of this pneumococcus serum by the inoculation of horses with ascending doses of pneumococcus cultures. It is difficult to keep the pneumococci virulent. Alternate generations of them are passed through animals for this purpose. The serum seems to protect against other micro-organisms besides the pneumococcus. The horse is very sensitive to streptococcus injections, yet in one case by mistake a horse immunized against pneumococcus was injected with 100 c.c. of virulent streptococcus culture without evil effect.

SECOND DAY—JUNE 6TH.

Pseudo Smallpox.—Dr. Happel of Tennessee described some cases of disease that have been occurring epidemically in the district in which he is health officer which have been called smallpox by the State board of Health of Tennessee but to him do not seem to be true smallpox. The differences are mainly that the constitutional symptoms of this affection are much less severe and it has practically no mortality. Then too this affection is always well on the eighth day just when the patient suffering from true and severe smallpox is beginning the fight for his life. In certain cases of this affection the eruption was of the confluent form yet no pitting resulted. In all of the cases the vesicular stage seemed to be the acme of the disease, pustulation did not occur and the cutaneous lesions disappeared by desiccation. The vesicles were always unicellular, never umbilicated; after being semi-spheroidal they became conical just before inoculation occurred. Vaccination seemed to exert no influence either on the occurrence, the course or the severity of the disease. After recovery vaccinations were successfully accomplished in a number of cases. While successful vaccination was running its course in a number of cases the vesicular disease supposed to be smallpox developed. Frequently in families where some were vaccinated others not the unvaccinated had the milder form of the disease. Many of the negroes objected to vaccination because it frequently incapacitated them for work for a week or 10 days while the disease gave discomfort only for a few

days at most. It came on with fever that reached at times 104° F. and was accompanied by severe pains in the back, headache and pains in the bones but all of these symptoms subsided on the second or third day and did not reappear later as they do in true smallpox. While genuine variola is very contagious this disease is not. In one instance children were sent to their homes from a crowded schoolroom after the vesicular stage of the disease had developed, they returned after two weeks, while the desquamative stage was in progress, yet none of the other children developed the disease.

Dr. Happel then said that he considers that the status of the present epidemic of so-called smallpox should be thoroughly investigated. Cases should not be labeled smallpox heedlessly for the results are apt to discredit vaccination and diagnosis. Certainly that has been the effect on public opinion in Tennessee.

Variola and Varicella.—Dr. J. J. Walsh of New York said that it must be borne in mind that the Vienna school of dermatologists, perhaps the most distinguished in the world, still insist that smallpox and chicken-pox are not essentially different diseases. Professor Senator of Berlin, who formerly believed in the essential distinction of these two diseases, has on many occasions in recent years expressed the opinion that they were related to each other. Varicella is for him variola modified by generations of vaccination and better hygienic conditions. Whenever he hears of varicella in Berlin he is almost sure to hear that some cases of smallpox have occurred in the city. Dr. Happel's skepticism then may prove most valuable for medicine if it will but encourage more careful investigation of this subject of cases intermediate between smallpox and chicken-pox by those who have the opportunities for the study of many cases of this atypical disease.

Vaccination in the South.—Dr. James of Missouri said that in his State the epidemic of smallpox had been allowed to spread by the foolish persistence of doctors in the diagnosis of chicken-pox after it had become evident that the disease was genuine smallpox. The salvation of the State had been accomplished by vaccination. This very soon put an end to the progress of the epidemic. In no case did it fail to do its saving work. The story of the recent epidemic in Missouri will prove an interesting chapter in the history of vaccination.

Smallpox Threatens the Country.—Dr. Chapman of Ohio says that while the doctors are quarreling over what name to call the disease the epidemic is constantly spreading. We have twice as much smallpox in the country now as at this time last year. Neglect of rigid precautions will surely result in a spread of the epidemic all over the country. Varicella does not appear in adults and wherever even the mildest cases of this disease has occurred it has always attacked adults rather than children. The talk about uncertainty as to the disease gives people a reason for neglecting quarantine precautions and tempts them to conceal cases. Vaccination is being discredited and we are in the face of more danger from a general epidemic of smallpox than any time in 20 years.

Dr. Stewart of Philadelphia said he did not think that the cases described by Dr. Happel were true smallpox. The most careful investigation of the subject is required, however, because of the danger to the country.

Dr. McCormack said that such papers as Dr. Happel's were sure to do harm. There is danger from temporizing with smallpox now, but the deliberate introduction of doubt as to the diagnosis cannot fail to work serious mischief. He asked for a censure by the section of Dr. Happel's views.

Dr. Happel in closing the discussion said that too many health officers diagnose smallpox without proper examination of the patient. In one instance the official stayed without the house and judged through the open door that a patient had smallpox. Dr. Happel himself had seen hundreds of cases of smallpox close up. He does not think the present epidemic in Tennessee is smallpox and feels that if doubt will lead to more careful study of the cases then good for medicine will accrue.

Yellow Fever.—Dr. Wasdin of the United States Marine-Hospital Service discussed the natural history of yellow fever. The disease used to be considered endemic in our Southern States, but the proper enforcement of maritime regulations has caused it to be generally recognized that it is always an importation. In the old days yellow fever was considered to be causally connected with certain meteorological conditions. The disease occurred so commonly and with such virulence in warm, damp weather that a spell of rainy warmth was often spoken of as yellow-fever weather. The disease always decreased when it was dry and hot or in cold weather. When yellow fever occurred sometimes at the North it was often noted that it did not cease promptly on the appearance of frost, while at the South it usually does. The reason seems to have been that at the North the germ of the disease found favorable conditions for its growth in the artificial warmth within doors. In the South, on the other hand, the first frost usually comes as a surprise and finds the people unprepared for wintry weather. As a result the germ finds no shelter from the temperature which is the same within doors as without.

The Bacillus Icteroides as Cause.—A number of bacilli have been described at various times as causative of yellow fever. In 1889 Dr. Sternberg was detailed to investigate the subject and repudiated all the supposed discoveries of bacilli pathogenic for the disease. He thought that perhaps it was not caused by a bacillus but some other form of organism. In 1897 Sanarelli announced his discovery of the bacillus icteroides. At first this discovery was not well received. Dr. Sternberg found in Sanarelli's bacillus certain similarities with a bacillus described by himself

and called for recognition purposes the bacillus X. Drs. Wasdin and Geddings were sent last year by the Surgeon-General of the United States Marine-Hospital Service to investigate the subject of the etiology of yellow fever anew. They found Sanarelli's bacillus icteroides in over 95 per cent. of the cases examined and consider that there now remains no doubt but that the bacillus described by Sanarelli is the cause of yellow fever.

Many denied the pathogeneity of bacillus icteroides for yellow fever, because the bacillus stands cold well while yellow fever always disappears with the first frost. Dr. Wasdin, working at the Pasteur laboratory, recently found that rabbits inoculated with bacillus icteroides died from septicemia in eight days if kept at a temperature of 77° F. and in eighteen days if kept at 60° F., and did not die if kept at the ordinary temperature of the outer air. In intensifying cultures by passing them through animals, it is very important that the animals should be kept at the higher temperature mentioned.

Mode of Entrance and Spread of Germ.—Dr. Wasdin considers that the bacillus icteroides finds its way into the system through the respiratory tract. Here it is colonized for a time and the system suffers from its toxins. Later it finds its way into the blood-stream and produces a septic condition. This is the real danger of the disease. If the tissues and blood are examined before the septic stage they will be found to be sterile. Animals are susceptible to the disease. The mouse, the dog and the rat are spontaneously susceptible, that is they catch the disease during epidemics without any special inoculation. White mice are so susceptible to the disease that they need only to be kept in the room where other animals are suffering from the effects of the bacillus icteroides and without any contact with them they contract the disease. The horse and cow are artificially susceptible, that is, they may acquire the disease by inoculation. Animals serve to spread the disease. Their respiratory secretions carry the infectious material and spread it over a neighborhood.

Demonstration of the Bacillus.—While Sanarelli first described the bacillus icteroides and gave it its name he found it in only about 55 per cent. of his cases of yellow fever. His demonstration of its specificity for the disease was most incomplete. The work of Wasdin and Geddings has really established firmly the status of the bacillus with regard to yellow fever.

In the discussion Dr. Flexner said that even the work, very creditable though it was, of Wasdin and Geddings did not entirely establish as yet the specificity of the bacillus icteroides for yellow fever. The invasion through the respiratory tract, when for so long it seemed certain that infection must take place through the gastro-intestinal tract, was also of great interest. This would have to be confirmed by other observers. As to the spread of infection through the lower animals, this is a very attractive hypothesis but nothing more. It is extremely difficult to judge of the susceptibility of animals. In the laboratory we overwhelm them with the doses we inject. It would be necessary to determine whether animals take the disease under normal conditions or not. This we cannot decide by laboratory experiments. In closing the discussion Dr. Wasdin said that certain animals at least take the disease under what are practically the normal conditions required by Dr. Flexner. Mice need only to be kept constantly in the laboratory where work is being done with the bacillus icteroides and they sooner or later contract the disease. They can scarcely be said to be overwhelmed by injections of too large amounts of culture.

Malaria Symposium.—The secretary read the paper of Dr. Jesse Lezear, U. S. A., in which present-day staining methods for the plasmodium were described. The estivo-autumnal parasite is especially difficult to recognize. It is small in size, of indefinite outline, hyaline and almost transparent. Staining makes it very easy to see it, however. Cover-glasses for staining for the malaria parasite need not necessarily be examined at once. After taking they may be kept without deterioration for a month if too much evaporation is not allowed to take place. Many forms of birds contain hematozoic parasites that form interesting side studies to the malarial organism because of the light they throw on its life-history. The crow often contains such a parasite both of whose sexually complete forms are actively motile.

Malaria and Mosquitoes.—Dr. W. S. Thayer of Baltimore read a paper on this subject, most of the material of which appeared in an abstract in the proceedings of the American Association of Physicians and Surgeons. With regard to the mosquito as the only source of malaria, he added to what was said before. By analogy with other diseases we would not expect more than one method of communication of the disease. In malarial countries people are apparently perfectly protected if they sleep beneath mosquito-netting. The mosquito always exists in malarial regions, at least so far as has been investigated. Where even the particular type of mosquito exists that conveys malaria, malaria is not necessarily present. If patients suffering from malaria come into the region, then the mosquito becomes infected and spreads the disease. Whether the mosquito can acquire the parasite from any other source than man is an interesting question that cannot be settled as yet. Probably not, however. This explains why malaria as far as is known was never acquired primarily in uninhabited regions. It also accounts for the fact which has often been noted that explorers, after escaping the dangers of malaria in the interior, are attacked by the disease when they reach the coast. Here the mosquitoes are more plentiful and they have abundant opportunities to obtain the parasites from those suffering from the disease. Reunion Island, a French possession off the African Coast, had no malaria until 1869. There were, how-

ever, plenty of mosquitoes. In that year a party of colonists came from India, some of whom had suffered from malaria there. After this malaria became endemic on the island.

Treatment for the Limitation of Malaria.—First keep all cases of malaria under mosquito-netting. The yearly course of malaria seems to be this: Cases that occur in the spring-time are relapses from old malaria. It is by feeding on these patients that the mosquitoes acquire their parasites. If the cases could be kept from the mosquitoes at this time the spread of the disease would be prevented.

Secondly, destroy the mosquitoes if not by some direct agent, then by something that will limit their numbers. The Anopheles mosquito, the malarial bearer, lays its eggs in stagnant water. If all pools of stagnant water were removed then the pest would not breed.

Varieties of Mosquito.—L. O. Howard of the Bureau of Entomology of the Department of Agriculture described especially the ordinary form of mosquito and the malaria carrier. The easily-recognized distinction between them is their different mode of resting on a ceiling. Anopheles, the malaria carrier, poses his hind feet out almost perpendicularly to the plane on which he rests; those of Culex are almost parallel to that plane. The wings of Anopheles also contain certain markings that are not on the wings of Culex. The two mosquitoes may be rather easily distinguished at every stage of their existence. In the wriggler stage Culex pungens has a long respiratory siphon, while Anopheles has but a short one. Culex goes down in the water to feed; Anopheles feeds on the surface. Their respiratory apparatus is adapted to their respective habits in this respect. Culex larvæ can live in small pools. Anopheles prefer those which have a green scum, as they feed on algæ of which the green scum is composed. In the pupa stage the head and thorax of Culex are much larger than those of Anopheles. In the adult stage, when examined with a glass, it can be seen that the palpi of Anopheles are much shorter than those of Culex. There are three projections from the heads of mosquitoes; the middle one is the bill, the two side ones are the palpi. In Culex these three structures are all the same length; in Anopheles the two side ones are short, as if amputated. The note given off by Anopheles is four tones lower than that of Culex. It is easy to recognize them by their note alone if attention is given to it. A jar-full of each of the mosquitoes makes it possible to be sure of this.

Mosquito in Winter.—Dr. Woldert of Philadelphia described the finding of Anopheles in December and January in Washington; in Philadelphia up to the end of October; on the snow in Vermont in February, and at various times during the winter even at the North. There is no need, then, for the mosquito to migrate for long distances. It may persist throughout the year even in high northern latitudes. It has been seen on several occasions and at various places within 500 miles of the North Pole. When mosquitoes are found during the winter they are always encountered not far from standing water and in the neighborhood of an animal. Dr. Woldert has found that where the pupæ of the insects occur they may best be destroyed by the use of a solution of tobacco in kerosene oil.

Estivo-Autumnal Malaria.—Dr. Craig, U. S. A., said that all the cases of pernicious malaria that have been described are of the estivo-autumnal type. The recognition of this form of the disease was delayed, because its parasite is not easy to discover. The plasmodium estivo autumnale is only one-sixth the diameter of a red blood-corpuscle; it has hazy, indefinite outlines and its rapid movement causes it to be difficult of perception. Red blood-cells affected by the entrance of the parasite take on a greenish tinge and the corpuscles lose their regular form and may become crenated. At times there are two parasites, or exceptionally more, in a corpuscle. It produces a typical temperature-curve with very regularly recurring paroxysms unless its course is disturbed, as is only too often the case by irregular, insufficient doses of quinine. This gives rise to an irregular, intermittent temperature-curve that makes the recognition of the disease from the chart usually so very difficult.

Clinical Observation of Malaria.—Dr. Frank Jones of Memphis pleaded for more clinical observation in malaria. Of late too much theory has crept into the medical literature of the disease. Resistance to infection from malaria depends, in Dr. Jones' experience, on the conditions of life. The well-fed and cared-for escape longer and when affected do not suffer so severely from the disease as the poorer classes. Brunettes suffer oftener than blondes. The negro, however, does not suffer from chronic malaria. People are liable to put on flesh even to become obese. The negro does not suffer from malarial hemoglobinuria. This is evidently a toxemia due to chronic malaria. In this malarial manifestation quinine should not be used

Malarial Hemoglobinuria.—Dr. Wm. Britt Burns, who has seen some eighteen cases of malarial hemoglobinuria, advises the use of quinine in the affection. For some years he treated malarial hemoglobinuria without quinine, but has reverted to its use with excellent results.

No Quinine in Hemoglobinuria.—Dr. Krauss of Memphis has treated in St. Joseph's Hospital, Memphis, fourteen cases of malarial hemoglobinuria without a death. This is a record set of statistics in the disease for this hospital in which many cases of the affection are admitted every year. In Dr. Krauss's opinion, malarial hemoglobinuria is a separate disease, or at least a symptom-complex. It is produced by causes which disturb the conditions of symbiosis that have been established between the host and the malarial parasite. For this disturbance quinine does no good. Stimulant supporting treatment is needed and gives excellent results.

(To be continued.)

SECTION ON SURGERY AND ANATOMY.

FIRST DAY—JUNE 5TH.

Surgery of the Stomach.—After calling the meeting to order the Chairman, Dr. H. O. Walker of Detroit, Mich., opened the scientific proceedings with a paper on the above subject, saying that the surgery of the stomach had to do with either benign or malign conditions. Among the former could be named congenital and acquired stenosis of syphilitic or other origin, foreign bodies, gastroptosis, muscular insufficiency, ulcer, and hour-glass contraction. The operations usually in vogue are pyloroplasty, gastro-enterostomy, anterior or posterior, of which the latter is the better. Instead of pyloroplasty, taking reefs in the wall is valuable especially in cases of gastroptosis which is so often associated with enteroptosis also. The author has seen but two cases of hour-glass contraction of typical form, each giving evidence of old ulcers as the cause. The early diagnosis of carcinoma by means of chemical examination of the stomach-contents and carefully searching for a tumor is the most important part of the case. If at all in doubt open exploration is necessary. Pylorectomy is available when the tumor is small, freely movable, and without adhesions. When this is impossible the posterior gastro-enterostomy is indicated to prolong life; it is most rapidly done with the Murphy button or with simple suture. The high mortality of these cases is due to bad technic, diagnosis so late that general decline has begun, and finally accidents and inexperience. Thorough and repeated lavage is a very necessary preliminary step. Non-perforating ulcers are often treated successfully internally, but if perforation have occurred then operate at once. The conclusions were in general that for benign conditions gastro-enterostomy or pyloroplasty, for malignant disease gastro-enterostomy, partial or complete pylorectomy, complete gastrectomy are the best methods. Exploratory incision is always justifiable.

Oration on Surgery.—This was delivered by Dr. W. L. Rodman of Philadelphia on the subject of "Non-perforating Ulcer of the Stomach." (See page 903.)

Dr. F. B. Turck of Chicago opened the discussion and said that the operative work on the stomach had at heart the removal of the benign or malign disease and the improvement of the patient. Among the non-malignant diseases amenable to operation are: (1) Pyloric obstruction from spasm of the pyloris without tumor; often these gave the worst symptoms from the active spasm due to the hyperchlorhydria and the multiple ulcers often about the antrum pyloris. (2) Gastric myosthenia which has resisted stimulation, gavage and electricity. Neuroses may underlie it and hypertrophy of the mucous glands, with overabundant mucus and much autointoxication, are usually distinct. (3) Hypertrophy of the muscle-wall or atrophy of the glands is another common condition with severe suffering. In general, a weighing of the probable local lesion against the condition of the patient, immediate and remote, a careful examination and exact diagnosis by all possible means were essentials. The speaker had had much success with instrumental and radioscopic examination. The contraindications are bad general condition, inoperable cancer, undue local disease, organic heart, liver and renal disease. Better diagnosis and improved management before and after operation would tend to improve results.

Asphyxia in Narcosis.—It had been the intention of the speaker, Dr. C. Fenger of Chicago, to read a paper on "Anterior Transverse Gastro-Enterostomy With Splitting of the Anterior Half of the Intestinal Wound." The plan had been to avoid persistent regurgitation of bile and death. In his first three cases he had succeeded, but failed in the fourth. Hence the method had failed of its promises. Attention was called to the procedure, recently followed at Bonn, of doing a gastrostomy at the same sitting and passing a tube into the descending loop of intestine and beginning the feeding at once. Too few had been done in this way to indicate its value.

As to dyspnea during narcosis and after operation about the jaws and mouth by falling of the tongue and epiglottis over the larynx, the speaker said that pulling the hyoid bone forward with a sharp hook is better than prying open the jaw and pulling the tongue forward. This method is applicable to cases of bony ankylosis of the lower jaw, of partial and total extirpation of the tongue or flow of the mouth, and of removal of the central part of the jaw bone, depriving the tongue of its anterior attachments. His preference is for a loop of silk passed about the bone through a small incision and then fastened suitably for support. His experiments on the cadaver showed that in the horizontal position the base of the tongue and the soft palate meet; with the head extended they separate slightly; still more if the tongue is drawn forward, if the jaw be now pushed forward the larynx comes into view, especially when the tongue is strongly pulled on; with the mouth shut pulling the hyoid bone forward opens the glottis freely, and traction on the tongue at the same time opens the throat best of all. In this way probably aspiration, bronchitis and pneumonia will be lessened, because when the throat is partially closed relatively small amounts of secretion do much harm.

Treatment of Cholelithiasis.—Upon this theme Dr. W. J. Menas of Columbus, Ohio, said that early diagnosis is important to avoid the complications and sequelæ of permitting a case to run on, sepsis, ulcers, contractures, folds in the ducts and chronic inflammation. There is no one symptom except finding stones in the feces which is absolutely certain. The author has had twenty cases; ten operated on with no deaths, and one faulty diagnosis; of the others three autopsies confirmed the diagnosis and two passed stones

and got well. The greatest number of stones he had ever removed was 230 and the largest quantity of pus was one quart. Recurrent colic, gastric disturbances, fever, rigors, nausea, vomiting, jaundice, pruritus, constipation, local tenderness over the colon and right kidney, pain in the abdomen and transferred to the shoulder, bile in the urine and local peritonitis were present in many or all of his cases. The prodromates had often been constipation, migraine, biliary urine, tinged sclera, ashy stools. Pain alone may come from inspissated mucus, cholecystitis and gallstones. In the latter the pain is brief, high up, and occurs three hours after eating and often is followed by nausea, vomiting and jaundice. Jaundice is often absent. Tenderness goes also with inflammation, tumor and stone. A floating kidney is movable and has the colon in front of it. The preventive treatment is to make the bile watery by giving salines, mineral water, calomel, rest and good diet. After the stones appear operation is usually necessary and at an early moment to prevent the stones doing harm.

Cholecystectomy and Removal of the Mucosa of the Gall-Bladder.—Dr. W. J. Mayo of Rochester, Minn., stated that radical removal of the gall-bladder was a necessity for gunshot and bad crushing wounds, for extensive phlegmonous, gangrenous inflammation and for malignant disease. For the permanent relief of obstructions of the cystic duct after a cholecystotomy, when the rest and drainage had failed to restore the lumen of the canal, one could choose a cholecystectomy or excise the mucosa down to the stricture. The former has many well-known risks. In his hands in 7 cases the latter had given good results. The technic is to approach the bladder through a new wound, respect all the adhesions formed for the primary operation, open the bladder below its fixation to the abdominal wall and peel off the mucosa down to the stricture, cut it across and then peel off the rest to the cicatrix. Drainage soon causes shreds of mucosa left behind to disappear, and the wound may then be closed.

Early Operation for Biliary Calculi.—There is a strong resemblance between the management of cases of appendicitis and of biliary calculi, said Dr. M. H. Richardson of Boston, Mass. The stones should be removed just as soon as the diagnosis is established to avoid the probability of the complications and sequelæ, suppurative cholecystitis, ulcers, contraction of the bladder, obstruction of the bile-ducts, etc. The earlier the operation is done the better the general local conditions for the surgeon and the patient alike, as in the appendix. The onset of cholchemia in obstructed cases is always bad. The conclusions reached were: (1) Operate early if the diagnosis is definite. (2) Explore early if it is doubtful to make it definite. (3) Facetted stones in the stools, with single or repeated attacks, operate. (4) Repeated attacks with or without stones in the stools, operate. (5) Continuous, repeated or great tenderness over the gall-bladder, operate. (6) Repeated moderate attacks, operate. (7) Non-facetted stone with a single attack, do not operate. (8) In short, regard the case exactly as an appendicitis and operate before suppuration, impaction, perforation and death can occur.

Second Day—June 6th.

Permanent Fecal Fistula.—One important detail of this procedure was amplified by Dr. J. A. Wyeth of New York City in case of permanent colostomy for inoperable conditions of the lower bowel itself or of the surrounding pelvic viscera which may occlude the rectum by pressure. The advantage of his suggestion lies in the fact that it may be carried out as part of any of the well-known methods of artificial anus formation. The point is simply to render the part of the intestine distal to the anus quite straight and short by traction upon it, then by traction on the proximal end create a large artificial loop whose dependency lies below the level of the opening and forms a pocket in which feces will store, as they do in the loop of the sigmoid colon. Only when this new sigmoid flexure becomes full will the discharge take place, namely, twice or thrice daily and usually in a manner to give the patient warning and avoid the unexpected flood of matter which make artificial ani so intolerable to the patient and to society. Dr. Wyeth prefers sutures to the glass-rod support. Further, he draws out eight or nine inches and by folding over and suturing the mesentery *en masse* to the bowel obtains a stiffening for the spur. Here silk running sutures are the choice. A knuckle three-quarters of an inch long is left exposed, the peritoneum is stitched all around to wound and to bowel, the skin is reinforced and after twenty-four to thirty-six hours the opening in the loop is made under cocaine.

Intestinal Exclusion.—This paper was read by Dr. John A. Evans of Chicago in behalf of Dr. J. B. Murphy of Chicago who was unable to be present. Its object was to show the present status of the Murphy button in intra-abdominal surgery. Up to April 1, 1900, there have been 1620 cases of use of the devise since eight years ago when Dr. Murphy first tried it on the human being. The statistics have special reference to the unfavorable cases and show a mortality of about 20 per cent. which with improved and early diagnosis, prompt and more skilful technic should be reduced in the future to 10 per cent. or less. Gastro-enterostomy by all known methods shows a mortality of nearly 39 per cent., with the button about 20 per cent. Entero-enterostomies without regard to the means used 60 per cent., with the button alone about 19 per cent. of all cases. There had been only eleven cases of cholecystenterostomy done before the button was introduced and 156 since. No deaths have occurred under its employment while the total rate is nearly 15 per cent. This list of 156 reports excludes 11 done by Dr. Murphy himself since 1895. The grand total of 1620 records has no-

respect whatever to the general and local condition of the patient, the knowledge, skill and experience with the button of the surgeon and goes back to 1892 when the invention was first published. The advantages of the button method, set forward by Dr. Murphy and now agreed with for the most part throughout the world, are (1) no suturing necessary; (2) great brevity of the operation; (3) edge to edge union of the same histological elements; (4) resulting cicatricial ring does not materially contract; (5) physiological processes of the intestine go on at once through the lumen of the button; (6) firmness of the union permits feeding to be begun at once; (7) adaptability to the gastro-enterostomies which are finding wider indications and more frequent performance; (8) readiness with which even the inexperienced may with care use it. The cases reported of contraction of the scar have been due to the invasion of neoplasm in the bowel adjoining. Failures have been due to faulty technic. The objections to the button are (1) that its canal may become plugged with feces; (2) that the button may be retained. No deaths due to retention are reported in literature. Eleven cases of plugging with three fatalities in the 1620 reports are known. The same device is now used with satisfaction in anastomosing the ureters with the intestines and with the bladder. Some forty modifications or parallels of the device are known, the more important of which were discussed.

Obstinate Constipation.—Upon this important difficulty Dr. J. R. Pennington of Chicago said that the portion of the intestine from the external border of the left psoas to the anus constitutes the sigmoid colon and the rectum. That which has a mesentery is the true sigmoid, that without is the true rectum. In the collapsed and cadaveric state the sigmoid occupies the left iliac fossa, whereas distended it may occupy the right. The degree of distention and the freedom and length of the mesentery govern its position. The rectum is divided into compartments by Huston's valves, varying in number but usually three and of similar shape, interesting the circumference of the intestine for half to two-thirds of its limits and directed mostly upward toward the colon. Prof. Evans of Chicago made numerous examinations, photographs of sections of these valves for Dr. Pennington and found that some contain all the coats except the serosa, others only the mucosa and submucosa and still many contained portions of either or both musculares to a varying amount. The tortuosity of the sigmoid, the irregularity and deformity of the valves and the hypertrophy of the musculares form the principal primary causes of obstipation by aiding in setting up chronic interstitial proctitis which prevents the secretion causing dry stools and stiffening the valves, converting them from a physiological intermittent obstruction to a pathological and constant one. The surgical removal of these valves by cutting was in one case attended by fatal hemorrhage in another by general peritonitis. To avoid these risks Dr. Pennington devised a clip which by pressure causes the center of the valve to necrose, leaving a deep notch and freely hanging halves of the formerly rigid continuous ridge of the valve. The clips and introducing instrument together with a proctologic table of his design were also shown. Numerous gross specimens, casts, colored plates and microphotographs made the points of the paper very lucid.

Dr. Tuttle of New York in the discussion said that he corroborated Dr. Murphy's claim that his metallic button could be indefinitely retained without damage. Dr. Wyeth's method of colostomy was good and probably realizes its aims, but he desired to emphasize its absolute restriction to the permanent artificial anus, because the carefully-constructed spur interfered with prompt reduction and necessitated opening the general peritoneal cavity, which should always be avoided in repairing artificial outlets. The speaker had often used the new method of Bailey of London and had excellent satisfaction. He prefers the glass-rod to any other form of support. In the rectum he had frequently demonstrated the existence of valves and regarded surgical treatment of them as often necessary.

Dr. Ellison of Illinois reported a case of a twenty-two-inch sigmoid with bad constipation.

Dr. Martin of Cleveland said that for six years he had treated the rectal valves as often pathologic and had examined and reported one in section in 1896. They caused hyperemia and dilatation of the sigmoid which often had to be diagnosed from simple catarrhal appendicitis. So-called annular stricture of the rectum is hypertrophy of the rectal valves: benign tubular stricture has, in addition, infiltration of the valve-base and adjoining wall with new lymphoid and connective tissue; non-malignant obstruction may arise from anatomical propinquity and overlapping of these valves. The consequences were straining at stool, dilatation and hyperemia of the sigmoid and intestinal autointoxication. Careful proctoscopy for diagnosis and valvotomy for treatment were his rule.

Repair in Intestinal Resection.—In the illustration of his points Dr. W. A. Evans of Chicago passed about slides and photomicrographs of end-to-end anastomosis, which was the true issue of his paper. There are no cases reported of secondary stricture after any of the methods of doing this operation and the danger appears to be very slight, especially when the Murphy button is employed. What contraction may occur is solely limited to the first six months. The only fibers which cause contraction of the scar are the circular ones, whereas the connective tissue fibers of the serosa, muscularis and submucosa are all longitudinal. Neither coat of the muscularis is found in the scar, hence, there usually is a depression in the mucosa to mark its site. The mucous layer in the Murphy button cases always forms a complete ring free of scar. The law is for scar-tissue fibers to arrange themselves always

along the line of tension, hence, in the gut lengthwise and in the heart with pull in all directions they have no definite arrangement. Again, the artificial opening closes only when not in use, namely when the original path in side-to-side union is again in function. Tubes subject to distention only have cicatrices, as the esophagus and urethra, while the small intestines have very rarely any, even after typhoid and tuberculous ulcers. In the Murphy button the circular fibers are cut lengthwise and have little or no pull on the scar; the longitudinal fibers are divided transversely and do pull but do not enter the scar-tissue as muscle-cells can not enter and bridge the new cicatrices. Entire apposition of peritoneum to itself is not as good as securing fibro-peritoneal apposition, usually stronger and just as prompt. The mucosa heals best and the muscularis least, hence, after ulcers we find the latter absent and the former completely restored. In general secondary stricture after end-to-end anastomosis is only a possibility, insufficient to contraindicate the operation.

Dr. F. H. Wiggin of New York discussed and supported the statements of the paper. As a rule, he prefers Maunsell's anastomosis without the lateral extra incision to the Murphy button.

Appendicitis.—Dr. Miles S. Porter of Ft. Wayne, Ind., rehearsed the frequency in which in his own experience and in literature simple acute and recurrent appendicites, with or without abscess, are preceded by constipation of varying severity and degrees of chronicity or by recurrent or chronic catarrhal colitis, which may extend into and modify the true appendical picture. Other causes of appendicitis seemed to be childhood and adolescence and the uric acid diathesis, all associated more or less with colitis. Again possibly rapid and too eager eating might cause gastro-intestinal disturbance, then colitis, and, finally, appendicitis. As to the treatment of appendicitis, the writer pleaded for moderation in searching for the diseased organ. Incision and drainage are better in severe attacks, large abscesses, and septic, anemic and enfeebled patients. It substitutes a brief mild operation for a severe and more or less prolonged one and gives as good or better statistics in this class of patients. Recurrence according to literature takes place in 13 per cent., which is probably too high. A second operation for ablation of the organ can then be done just as safely as at the first sitting. To make all operations primary appendectomies would increase the mortality.

Appendicial Fistulæ.—Dr. J. B. Deaver of Philadelphia said these dreary sequelæ of appendicitis are not uncommon and unimportant to the surgeon and patient alike in the effects on the system and locally according to the organs involved. They always menace health and are avoided by early operation. There are two types, the internal and the external. The simple external fistulæ are practically sinuses going down to the bowel caused by foreign bodies, like gauze, too much drainage-tube, and the like. They may have the lumen of an appendix, otherwise shut off from the cecum, discharging into them a mucous secretion. The fecal external fistulæ open at once into the bowel, either appendix or intestines, large or small, and at any point. Internal fistulæ open into any hollow viscus, rectum, bladder, ureters, bronchi or pleura. The complications following such a rupture make it anything but a desirable solution of the difficulty. The causes are usually abscess formation, migration of micro-organisms, separation of the appendix, too many or too tight sutures, too long use of drain-tubes, pressure necrosis. Early radical attack on the appendix cures and prevents the fistulæ. If the regulation of diet for solid feces and locally ordinary cleanliness and rest did not cure simple cases, exploration for the offending gauze or suture with curetting of the tract is indicated. If it lead down to an old abscess-cavity the usual wide-open method for healing from the bottom should be followed. In fecal fistulæ remove the remains of the appendix, break up adhesions, close the gut or resect and anastomose. Very many fistulæ close spontaneously if left alone, hence, excepting where the small intestine high up is involved and the nutrition is suffering, leave them alone to see what Nature will do. In general the best cure is the prophylaxis of operation in all cases of appendicitis as soon as the diagnosis is made.

Dr. Senn of Chicago opened the discussion and said 80 per cent. of all cases of appendicitis get over their first attack and of these half never have a recurrence. To operate on each case would, hence, be an error. Spontaneous rupture of abscesses into the cecum had best be left alone.

Dr. Price of Philadelphia agreed in the radical immediate operation as a rule. In the bad cases he likes free incision, irrigation and drainage with only gauze through an unsutured wound, after the colon has been widely freed and brought directly beneath it to make the drainage-tract free and straight. He reported 3 per cent. mortality with this method.

Dr. Dawbarn of New York said preservation of life is best done by the immediate primary operation. Fistulæ may be prevented by passing a purse-string suture wide of the appendical stump in sound bowel. Inversion of the gangrenous part, while the suture is tightened, is the last step.

Dr. Hamilton of Columbus, Ohio, spoke of the importance of counteropening in the loin if drainage were doubtfully efficient.

Dr. Mynter of Buffalo said portal pyophlebitis was a more important sequelæ of appendicitis, because fistulæ tend to close themselves.

Dr. Keen of Philadelphia said no rule can be laid down, but that he preferred to regard each case as a law to itself as to when to operate, but no case should be allowed to go beyond two invasions.

Dr. McRae of Atlanta, Ga., had had recurrence of the inflammation in 75 per cent. of his cases of simple incision and drainage and had

seen practically all develop hernia within three years. Hence, early operation is best. Fistulæ had been well treated by him by invasion of the intestinal lesion and suturing over it with four or five layers of sutures.

Dr. La Place of Philadelphia, Dr. Murphy of Chicago, Dr. Gray of Jersey City, Dr. Boldt of New York, and Dr. W. Easterly Ashton of Philadelphia all agreed in the necessity of primary operation at the time of diagnosis as no one can foresee the results of delay.

(To be continued.)

SECTION ON OBSTETRICS AND DISEASES OF WOMEN.

FIRST DAY—JUNE 5TH.

A Review of Obstetrics and Gynecology.—The address of the Chairman, Dr. W. E. B. Davis of Birmingham, Ala., was in the main a general review of the progress in obstetrics and gynecology during the year. He stated that obstetrics cannot be practised with absolute success except by the obstetric surgeon, the gynecologist. He strongly advocated the use of rubber gloves in obstetric work, and believed that no obstetric complication existed that could not be successfully dealt with with gloved hands. We should as a nation learn from the experience of Austria and Germany. There the teacher of obstetrics is also the teacher of gynecology. This is also true in England. More than fifty per cent. of the cases coming to the gynecologist are obstetric in origin, and when this fact is borne in mind it will be clearly recognized that the two branches should be associated in the one man. In the near future he believed that there will be fewer specialists but more learned. This he regards as an indication of progress. It is difficult to obtain the *tactus eruditus* even with much experience. How, then, can the general surgeon be able to recognize cases which are often obscure even to the most expert gynecologist? The exalted position which gynecology holds in this country is due largely to the special journals devoted to the subject and to the national associations devoted to this line of work, including the American Gynecological and Obstetrical Association, the Association of American Obstetricians and Gynecologists, and the Southern Association of Gynecologists. In the latter organization are included the leading surgeons, obstetricians and gynecologists of the South. Its Transactions have been complimented both at home and abroad, and include contributions from eminent men, such as Battey, McDowell and Hunter McGuire. Battey's operation was a great mistake, but his influence on gynecology was positive and widely felt. Still, his teaching has probably been productive of more harm than that of any other man. Through his influence the neurologists were driven to the opposite extreme and repudiated operations that were fairly and urgently indicated. Undoubtedly in many instances in which there are marked neuroses, they have developed in women so predisposed, but all cases are not of this nature. Too much has been claimed for vaginal section, yet it has a large field. Peri-uterine and parovarian abscesses should be drained by this method and then, if need be, abdominal section should be performed later. It is gratifying to note the increasing popularity of the round ligament operation. A patient should not be compelled to wear a pessary when the safe operation can be done. If need be the abdomen may be opened in these cases and the round ligaments shortened in that way.

Surgery of the gall-bladder and gall-duct has been much improved during the last few years. The methods of closing the abdominal incision have never been satisfactory. The majority of operators still employ the through-and-through method. Others use the tier sutures. The author is in the habit of uniting the aponeuroses and muscle by tubes threaded with silkwormgut secured by shot; the fat is closed around the tube, and the skin united by silk or silkwormgut.

The Value of the Angiotribe in Vaginal Celiotomy.—Dr. J. H. Carstens of Detroit read a paper on this subject. He stated that conservative surgery is now predominant and that efforts are made to preserve as much of the pelvic organs as possible. Through the work of the French surgeons vaginal surgery has come permanently forward, but now the time has come when the surgeon selects his cases for either route. The author prefers vaginal celiotomy, but has encountered one great obstacle, *viz.*, the tying of the broad ligament so that hemorrhage will be controlled. He has tried the clamp and has seen sloughing follow with prolonged convalescence. The angiotribe has greatly simplified matters. Take, for instance, the case of a young girl with an acute displacement and prolapsed and adherent ovaries. In these cases he prefers to do a vaginal celiotomy, remove the ovaries and apply the angiotribe. He made a study of this instrument last year in Europe and now employs it in abdominal and vaginal hysterectomy without ligatures. He does not endanger his patient's life in doubtful cases, however, by not using ligatures. The best cases for the angiotribe are small ovarian cysts, pus-tubes, and inflamed appendages. He believes the angiotribe will do more to lessen suffering and death than any other instrument recently devised.

Angiotripsy in Abdominal Surgery.—This was the title of a paper read by Dr. H. M. Taylor of Richmond. His experience sustains that of others. The instrument is easy to use and safe as to results. Post-operative pain and shock are less severe in character and less lasting, and convalescence sets in sooner. He has had no bad results. Only once has he failed to secure perfect hemostasis. He has used the angiotribe by the abdominal route only in ten or fifteen cases during the past year. He has not used it in septic cases, because he has not had any such cases. He applies the instrument for a period of three minutes.

Improved Technic in Major and Minor Surgery.

—Dr. H. P. Newman of Chicago read a paper with this title. He stated that we owe to anesthesia, hemostasis and antisepsis the great improvement in modern technic. The least possible violence should be done to delicate structures to secure the best results. Bad results follow improper dilatation of the uterine os, resulting in tearing which leaves scar-tissue that will not dilate at subsequent labors. Improper curetting is also a source of much evil. He judges a gynecologist not so much by the manner in which he does a hysterectomy as by the way in which he does a curettement. He especially advises care in the performance of tracheloplasty. Fissures, fistulæ, sinus and the like, should be dissected out entirely. In his experience the best results follow this method. In vaginal hysterectomy he has used the angiotribe with good results. He was the first to introduce this instrument in this country. He believes it is even more valuable in abdominal section. The instrument should be faultless in make and well tested. It should not be used in fragile tissue, the stump should not be handled after the angiotribe is removed, nor is it necessary to cauterize the stump nor to use drainage. In softened and edematous tissue there is some danger of tearing, as with the use of the ligature. The instrument requires the same care in use as do other instruments.

Dr. Wathen of Louisville thought that trouble follows the use of too many instruments. He has not used the angiotribe, but he recognizes the fact that there may be a field for it. He believes, however, that it prolongs the operation, especially in cancerous cases.

Dr. Goffe of New York has had a little experience with the angiotribe and desired to say a good word for it. He has found that it simplifies operations *per vaginam* and is perfectly safe. He tested it in two cases of advanced carcinoma involving the broad ligament and found that even in cancerous tissue it acted just as well as in sound tissue. He recently resected a cancerous rectum through the vagina, dragging down the rectum. It was necessary to restrict the mesentery, which he did with much satisfaction. In cutting off the rectum he first pinched it with the angiotribe and then stitched the end of the rectum to the skin, and had no oozing or hemorrhage. The angiotribe has a wide range of application. He has also used it in hemorrhoids. It is easy to handle. He learned its use in one and a half or two minutes. The instrument he employs is Tuffier's.

Dr. Bovée of Washington was glad to hear such good results from the use of the instrument. He does not think that the operation is shortened by the use of the instrument, which he considers a clumsy tool. The French journals have recently reported a number of deaths from hemorrhage after its use, and yet the instrument was devised to prevent this accident.

Dr. Ashton of Philadelphia will not use the instrument, since with it it is impossible to get the same support of the broad ligament in hysterectomy which follows the use of ligatures. He does all his work by the abdominal route. He emphasized the fact that care is necessary in the technic of curettement and dilatation. If the dilatation is made too rapidly laceration will follow. It should be slowly performed, the operation requiring at least ten or fifteen minutes.

Dr. Porter of Indianapolis wished to know how to apply the angiotribe and which instrument to use. He has had a case in which fatal hemorrhage followed the use of the instrument. He would like to know how many pounds of pressure should be employed and how long the process should be continued.

Dr. Boldt of New York has used the angiotribe since it was introduced by Dr. Cleveland. It will undoubtedly control hemorrhage, but it is not in the least degree superior to ligatures. He feels more secure with the use of the latter than with the use of the angiotribe, and in his experience the operation is prolonged by the use of this instrument.

Dr. Carstens, in reply, stated that he will use any instrument which gives him good results. He does not remove healthy ovaries nor those which are but slightly prolapsed, but if these organs give pain or are much displaced, they must come out. He considers the angiotribe invaluable in hysterectomy in certain cases, but does not think it is useful in cancer of the uterus. In such cases he prefers clamps, and in other cases ligatures.

Dr. Newman stated that he performs a tracheloplasty, or plastic operation, on the cervix and not trachelorrhaphy. He does not confine himself to any one plastic operation. He does not think time is lost by the use of the angiotribe. It facilitates the operation, gives perfect hemostasis, and does away with the use of ligatures. If hemorrhage occurs immediately after the removal of the instrument, he would apply a ligature.

Myofibroma Uteri.—Dr. H. J. Boldt of New York read a paper with this title. He stated that the histogenesis of fibromyomata is still disputed. He believes that they arise from the muscularis and are pure myomata. Fibrous connective tissue is absent until the tumors reach the size of 4 cm. A variety of the dermoid tumor—the adenomyomata—has given rise to much discussion. If these spring from the endometrium, they lie centrally in the uterine wall and show the tissue of the endometrium. The greater number of adenomyomata have their origin in the Wolffian body. Cullen described three cases and agreed with the views of von Recklinghausen as to their origin. If a fibromatous uterus be examined the endometrium will be found most dense. The muscular wall undergoes hyperplastic changes, and inflammatory changes are found in the tubes and ovaries. Various changes may take place in fibromyomata. They may disappear without treatment before the menopause and after parturition. Sarcomatous degeneration must be considered the most serious change.

In lymphangiectatic myomata there is much danger of the walls of the lymph-vessels becoming sarcomatous. Inflammation, gangrene, and other degenerations may take place in the tumor. If a symptomatic cure can be secured in cases of these tumors the radical operation should not be done. The social standing and the age of the patient should be considered. Thyroid and mammary extracts will control some of the symptoms, but do not greatly affect the size of the growth. Electricity in the form of galvanism has a limited use in the treatment of fibromyomata.

Arhythmia Cordia Complicating Fibromata Uteri.—Dr. J. W. Bovée of Washington read a paper on this subject. He stated that the complications of fibromyomata are becoming constantly more numerous. A condition of arteriofibrosis is considered by many to be present in their growth, but he has not noted its presence in any case. Organic cardiac disease is often associated, but cardiac symptoms are rarely present. He noted in the case of a colored woman with a large fibroid an irregularity of the heart-action and pulse. The heart was otherwise apparently normal. Cardiac tonics and rest in bed gave no result. Under the influence of ether the action of the heart became regular, but the irregularity returned upon recovery from anesthesia. Different forms of arhythmia are reported and these may be associated in the same patient. Their presence does not contraindicate operation, but the patient should be clearly watched and the ether administered with care.

SECOND DAY—JUNE 6TH.

Parturition as Factor in Gynecic Practice.—Dr. J. M. Duff of Pittsburgh read this paper. He said that parturition is the principal factor in the production of the morbidity encountered in gynecologic practice. He considered that over 50 per cent. of all gynecologic cases can be charged to parturition. This includes the large number of cases resulting from abortion. Aside from inversion of the uterus and fistulæ due to pressure, nearly all of the cases are primary, resulting from laceration, sepsis, or both combined. An important question is, What are the best means of avoiding these primary cases? Modern obstetric and surgical aseptic practice has done much to correct the trouble. He believes that more than 50 per cent. of all gynecologic cases would be eliminated were thorough asepsis adopted and at the same time the obstetric technic improved. In nearly every case of postpartum sepsis there has been some defect in the technic, a defect of omission or of commission. Occasionally the nurse, the friends of the patient, or the patient herself, will be at fault. The laity is largely of the opinion, and erroneously, that lacerations of the birth-canal are always the result of carelessness on the part of the obstetric attendant. This belief is fostered by certain practitioners who claim that they never have a tear in their practice and have never seen one. It is no disgrace for lacerations to occur, although complete laceration of the perineum is rare in the hands of an accomplished obstetrician. A slight laceration in primiparæ is the rule rather than the exception. Such tears should always be reported to the patient and an attempt made at repair. This operation will not always succeed primarily, but the effort should be made. A laceration of the cervix should also be repaired at the earliest possible moment after labor. If these cervical tears are not repaired morbidity will result. The day of antiseptic midwifery is past. Its principles are not only harmful, but absolutely dangerous. The true antisepsis consists in a normal condition of the excretions and secretions of the body and true asepsis consists in maintaining a normal condition of these functions. Antiseptic douching of the vagina is both harmful and dangerous. If the vagina must be cleansed it should be scrubbed, not douched. The vulva is the normal habitat of germs and it should always be thoroughly cleansed. Care should be taken to remove the placental tissue in full in every case. This precaution should include all placentæ succenturiatæ and plancentæ spuriæ. These extra placentæ are much more common, he believes, than is generally supposed. The routine practice of administering ergot after labor is pernicious and frequently results in the development of gynecologic troubles.

Dr. M. Price of Philadelphia wished to endorse heartily the method of antiseptic treatment as advocated by Dr. Duff. In nine cases out of ten puerperal sepsis results from the useless adoption of chemical antisepsis. Intra-uterine irrigation and the use of the curette after labor are often productive of fever. The finger is the safest guide. The mortality of women to-day is greater than at any time in the thirty-two years of his medical experience.

Dr. Dunning of Indianapolis thought that Dr. Price had stated his case a little too forcibly. He had, however, seen some of the pernicious results of intra-uterine douching unnecessarily adopted. Displacements of the uterus due to subinvolution is a common condition. This subinvolution can be largely prevented by a restoration of a lacerated cervix at the proper time. An examination of the patient should be made at the expiration of six weeks and if the laceration be found it should be repaired at once.

Dr. Joseph Price of Philadelphia said that the mortality of obstetrics at present is larger than formerly, due to a mixture of gynecology and obstetrics. With Parvin there died the last obstetrician in America. The present obstetricians are largely gynecologists. What is needed today are enthusiastic obstetricians. The syringe as found in the household, and which is even known as the "household" syringe, to be used by all the members of the family, is a great source of infection.

Dr. Miller of Syracuse said that mixed infections and most cases of pure streptococcic infection will die as a rule, while infections from the

bacillus coli communis and the saprophytes will generally be recovered from. As to the best treatment of these cases he would endorse serumtherapy.

Dr. Tuttle of Massachusetts would especially urge the careful preparation of the patient before delivery, including the use of the antepartum douche. This preparation should be carried out just as carefully as for an abdominal section or a vaginal hysterectomy. Secondly, a careful investigation of the parts should be made immediately at the close of labor to discover lesions of the birth-canal and retained products.

Obstetrical Advances of the Last Half-Century.—Dr. A. H. Halberstadt of Pottsville, Pa., stated that he was within a few months of completing his fiftieth year in medicine. During this time gynecology has made the advances and obstetrics, with but few exceptions, has been at a standstill. The Transactions of the Obstetrical Societies are now almost wholly gynecologic. Before and during the time of Hodge and Meigs the Chair of Obstetrics was the leading one, due to the personalities of the men who filled it. The two most remarkable events of the half-century are the introduction of anesthesia and asepsis. To these may possibly be added symphysiotomy. Anesthesia has not been generally adopted on account of the fear of post-partum hemorrhage. He stated that anesthetics cannot possibly do any harm in childbirth and cannot fail to do good. The condition of the heart and lungs should contraindicate the administration of ether.

Pelvic Disease and Nervous Affections.—The symposium on the relation of pelvic and intra-abdominal diseases to nervous diseases was opened by a paper read by Dr. H. O. Marcy of Boston entitled "Causal Relation that Intra-Abdominal Diseases Bear to Nervous Disturbances Recognized by Gynecologists, but Ignored by Neurologists." He stated that genius, if developed too far, may become eccentricity and ultimately mental derangement. The wise gynecologist should be a physician, surgeon, and neurologist as well. For many years he has advocated the study of the pelvic organs in the insane. He enlarged on the importance of the physiologic function of the reflex action of the nervous centers in health. The normal relationship includes afferent fibers, nerve-centers, and efferent fibers. The deep reflexes are of but limited value. There are certain groups of symptoms that are indicative of local lesions. These he considered in relation to their bearing on the reproductive organs of woman in health and in disease. A careful knowledge of the pathologic reflexes is of the first importance in the proper differentiation of organic lesion in the pelvic structures.

Menstrual Autotoxic Neuroses.—Dr. Arthur Johnstone of Cincinnati presented this paper. Every healthy child-bearing woman has a superabundance of nourishing material in her blood which must be disposed of in some way. This material is given to the child *in utero* and after birth is also received by the child during the process of lactation. When menstruation returns the excess is disposed of in the menstrual flow. A superabundance of nourishment in the blood, not to mention an additional quantity in the intestinal tract, is a very dangerous condition for both man and beast. If the fetus does not consume the excess the mother must get rid of it. The first symptom of this dangerous condition is kidney breakdown. If the eliminating organs are acting well the material will be effectually handled. There are individuals, however, whose emunctory organs are deficient, and these are the patients who develop nervous troubles and eclampsia. In young girls with faulty menstruation the symptoms are due to the failure of elimination of the excess of nutritious substances in the system. This is true of all nervous symptoms shown by gynecologic patients.

Traumatic Malformations and Insanity.—Dr. George H. Noble of Atlanta, Ga., said that neurologists have much more opportunity to see pelvic cases in the insane than have the gynecologists. In reply to the question indicated by the title of the paper which he sent to various neurologists throughout the country, some said directly "No." Others claim that only indirectly does traumatism react upon the mind, and others still that the action is direct and removal of the cause results in a cure of the mental and nervous symptoms. Gynecologists do not operate for the insanity, but to relieve the bodily sufferings. Accidents from childbirth, sepsis, adhesions and masturbation are some of the local traumatisms associated with the mental and nervous condition. The general obstetrician and practitioner should make a search for these local conditions. He has never personally seen mental defect associated with any form of double uterus, although authorities speak of this complication. Price says heredity is rare as a cause. Others say it is a common factor in the production of the mental and nervous diseases. The probability is that a bad family history is common in this condition. Aside from personal observation the author's paper was based on many replies received from alienists and gynecologists of the United States relative to the subject. He concluded that traumatisms and malformations of the female genital apparatus are indirect or exciting causes of insanity. Many operations have been done with satisfaction and uniformly good results. No special form of insanity follows the above condition. Some institutions make a practice of examining the women for these local causes and are giving much attention to the gynecologic side of the question.

Dr. H. A. Tomlinson of St. Peter, Minn., spoke of a third element in the equation between pelvic disease and disturbance in the nervous system in women. He tried to show on general principles and by statistics that the essential element in the association of disturbances of the nervous system in women with pelvic disease, abdominal operations, and the like, is an unstable or defective nervous system in the woman. This may be de-

fined as the nervous potentiality of the woman. The fact that most do not become insane or develop any of the chronic neuroses shows that the disease or operation itself is not the direct cause of the nervous disturbance. He cited cases and presented other evidence to show that those women who develop the different neuroses in association with pelvic disease and after operation have a definite history of unstable nervous equilibrium or actual defect in development. The proof of this is furnished by the life-history of the female, the natural history of maternity, the influence of civilization and environment in modifying the process of generation in women and the effect of these changes on an unstable and hypersensitive nervous system. He reported five cases recently admitted to the hospital of women who had been operated upon and a part or all of the generative organs removed. None were improved as far as the mental symptoms were concerned. In primary degenerates, *i.e.,* those who become insane during the period of adolescence, the generative organs show all of the changes of senility. Puberty is delayed in these cases, the advent occurring at about seventeen years of age. Menstrual troubles and pelvic disease are often associated with neuroses, but bear no causal relation to the mental condition.

(To be continued.)

SECTION ON DISEASES OF CHILDREN.

FIRST DAY—JUNE 5TH.

Serum Treatment of Diphtheria.—The Address of the Chairman, Dr. Edwin Rosenthal of Philadelphia was devoted to a consideration of this subject. He stated that the position held by antitoxin in the treatment of this disease is due to the pediatrist. During the past year he addressed more than 4000 communications to physicians asking their views on antitoxin. The replies show a practical unanimity regarding the value of this agent. Statistics from the health boards and hospitals in 157 cities give a mortality of 38 per cent. without antitoxin, and 14 per cent. when it was used. A comparison of the antitoxins manufactured by Parke, Davis & Co., Mulford, and various other reliable firms, showed that all standard makes are good. The laboratories and methods are open to inspection and the ethical standards of the firms are high. The admission of diphtheria antitoxin to the pharmacopœia should be supported by all. The suggestion was made that the next executive committee investigate typhoid fever.

The session was devoted to papers upon feeble-minded children and nervous diseases.

Etiology of Idiocy and Imbecility.—Dr. Martin W. Barr of Elwyn, Pa., gave the results of a fifteen years' study of these conditions. The causes were grouped under heredity, malnutrition, and accident. Statistics were given from his own studies of 3040 cases and from other writers, showing the effects of heredity. In his own series 13 per cent. had a family history of imbecility and 5 per cent. of insanity. He fails to find consanguineous marriages a cause of imbecility, unless there is a neurotic tendency of some sort in the families of the parties who marry. There is a danger in such relatives marrying. Only 1 per cent. of his cases came from consanguineous marriages and he regards such union with but little apprehension when there is no family taint. The law should not lop off the branches of the tree by forbidding these marriages, but should begin at the root by forbidding the marriage of persons having a neurotic taint. Figures showing the relation of various neuroses and malnutrition following disease as etiological factors were given. There was a history of phthisis in 9 per cent. of his cases and of intemperance in 3 per cent. Under the head of accidents instrumental delivery seemed to bear a causative relation in 1 per cent.

Care of Higher Grades of the Feeble-Minded.—Dr. A. W. Wilmarth of Chippewa Falls, Wis., classes as of higher grade those cases in which the faculties which enable one to carry on the ordinary social duties of life are defective or wanting. Moral imbeciles also belong to this class. The distinction from a backward child is made by the development of the powers reaching a point where progress is stopped instead of only being slow. Treatment is best carried out in an institution where there is rivalry and the humoring of the family is not present to dull the activity of the child.

In the discussion Dr. Leszynsky said that the treatment was pedagogical and must be carried out by an institution or by persons at the home. Under proper conditions such individuals do better at home.

Dr. J. Madison Taylor said that he formerly believed the home treatment to be the best, but since studying the results of institutions he had changed his opinion. Such cases do better with others of the same degree along side of them as a stimulus. Great wealth might in a few cases give good results in the home, but for average cases institution training gives much better satisfaction.

Study of the Circulation in the Feeble-Minded.—Dr. J. Madison Taylor read for himself and Dr. F. S. Pearce of Philadelphia the results of a study made on 935 children in the Pennsylvania School for Feeble-Minded, the lowest forms of idiots being excluded and only those taken in which there was a suspicion of circulatory disturbance. Of this number 72 were found to have definite lesions of the heart or vessels. 40 males and 32 females. In the majority of cases the vasomotor system was most at fault. As treatment of cardiac and circulatory defects causes an improvement in the condition of such patients, the recognition of the condition in early life is important.

In discussing this question Dr. Leszynsky stated that he did not consider that Dr. Taylor had proved his point. The circulatory disturbance is more likely a result than the cause.

Infantile Cerebral Palsies.—Dr. A. C. Cotton of Chicago classes under this head all conditions of impaired function due to a cerebral disturbance, even if there is no motor paralysis present, as in epilepsy, etc. A report of 25 cases was made. Of these 18 were females. The time of onset was before or at birth in 17 cases. Of 11 diplegic cases, 7 were idiots; of 8 hemiplegics only 2 were idiots. In only 2 cases were there athetoid movements and both of these were diplegics. In one diplegic there was no mental involvement, although other typical symptoms were present.

In discussion Dr. Leszynsky stated that every child suffering from epilepsy should be examined for the possible existence of cerebral palsy. A certain number of cases recover partially and attention is not called to the condition until epilepsy develops, when the parents bring the child for treatment. The presence or absence of cerebral palsy has a decided bearing on prognosis in such cases.

Dr. Griffith emphasizes this point and said that physicians often made mistakes by not attributing epilepsy, etc., to cerebral palsy. He called attention to the rarity of tremor as a post-hemiplegic symptom.

Dr. Cotton stated that the percentage of cases of improvement at home is very low and he is anxious to hear from institutions. One postnatal case, occurring at six months of age, has been watched by him, the man now being twenty-four years of age. He can use carpenter's tools and play in a band, thus being self-supporting.

The following papers were read by title: "The Importance of the Education of the Sense of Touch in Feeble-Minded Children and its Connection with Manual and Industrial Training," Dr. Fletcher Beach, London, England; "Physiologic Training of Feeble-Minded," Dr. S. J. Fort, Ellicott City, Md.

(To be continued.)

REVIEWS.

A Practical Treatise on Sexual Disorders of the Male and Female. By Robert W. Taylor, M.D. Second Edition. 8vo., 438 pages. Illustrated. Lea Brothers & Co., New York and Philadelphia.

It must be highly gratifying to Dr. Taylor that a second edition of his valuable work on sexual disorders has been so soon demanded by the profession, who, realizing the great value of his writings, will read with pleasure and much profit the present edition, which treats of these affections, both in the male and female in a masterly, scientific, and at the same time eminently practical manner. The various methods of treatment are given in detail, and will be found of great practical value to the general practitioner and specialist as well.

The chapters on the anatomy and physiology of the sexual apparatus have been thoroughly revised and enlarged, as have also those devoted to sterility and sexual disorders in the female, which conditions are most satisfactorily dealt with in every respect, thus adding greatly to the value of the present work, in which the author deals with these peculiar affections in his usual clear, concise and practical manner, the result of careful and extended pathological research, together with an extensive and closely observed clinical experience.

The relation between chronic urethral inflammations and affections of the prostate gland and seminal vesicles to sexual impairment and debility is most clearly and convincingly brought out, and in these chapters much that is new, original, and interesting will be found.

After a careful reading we take great pleasure in recommending this standard and authoritative treatise to the student and practitioner, both of whom will be fully repaid by a perusal of its pages.

The book is profusely illustrated with new and well-executed colored plates and also half tones, the vast majority of which are from the author's personal cases.

The publishers, Messrs. Lea Brothers & Co., are to be congratulated on the general make-up and appearance of the book, which is all that could be desired.

Nervous and Mental Diseases. By Charles S. Potts, M.D., Instructor in Nervous Diseases, University of Pennsylvania; Assistant Neurologist to the University Hospital, Philadelphia. Lea's Series of Pocket Text-Books. Lea Brothers & Co., Philadelphia and New York.

Whatever in the way of derogation or of praise that may be said of small manuals, the fact remains that for beginning students and for a large number of general practising doctors, such manuals, if conscientiously and ably prepared, are of very great service.

The exact proportions to be devoted to the different aspects of the subject are difficult to determine, yet in a book of this kind we believe that the author has been wise in devoting himself more particularly to general symptomatology and methods of examination as well as in the giving of a large amount of space to treatment. It can hardly be said that the chapters on mental disease are adequate. The chapter on hysteria is especially full, but in a country where this disease is comparatively rare, especially in its severer grades, the amount of space given seems out of proportion. Apart from such consideration, however, the work is an excellent one. It is convenient in size, its information is accurate and well digested and the mechanical execution commendable.

The work can be recommended especially to the beginning student who should not, however, rest content, for his knowledge of nervous diseases, on such an elementary manual.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXXVI. NEW YORK, SATURDAY, JUNE 16, 1900. NO. 24.

ORIGINAL ARTICLES.

THE PROPHYLAXIS AND CONTROL OF LEPROSY IN THIS COUNTRY.[1]

BY PRINCE A. MORROW, M.D.,
OF NEW YORK.

IN this paper, which has been prepared at the request and, I may even add, the urgent solicitation of the President of this Association, I have not the pretention to suppose that I have solved the difficult problem of the control of leprosy in this country. My object has been simply to offer a few suggestions, based upon my observation and study of the disease, with the view of eliciting the opinions of the members upon this important subject.

Unfortunately, the leprosy question in this country has been chiefly agitated by alarmists through the columns of the daily press. It seems to me desirable from every point of view that the discussion and decision of this purely sanitary question should be transferred from the arena of sensational journalism to the higher tribunal of scientific medicine.

It is worthy of record that this Association was the first among the scientific bodies of this country to call attention to the prevalence of leprosy in the United States and it has been the most active and persistent in urging upon our legislative and sanitary authorities the importance of taking suitable measures to prevent its further development and spread. Our distinguished confrère, Dr. James C. White, was the pioneer in this movement. As early as 1878—a period when leprosy was scarcely recognized in the nosography of this country—he presented statistics showing that the disease prevailed to an extent hitherto unsuspected. In 1882 he again presented a paper upon this subject and urged the necessity of repressive measures to check the evil. It was, I believe, at his suggestion and through his influence that the subject of the "Distribution and Control of Leprosy in North America" was made the topic for discussion before the general session of this Congress at its meeting in 1894.

As a result of this and other efforts to secure legislative action an "Act for the Investigation of Leprosy" was passed by the Senate and House of Representatives April 22, 1898. Under its provisions the Supervising Surgeon-General of the Marine-Hospital Service was empowered to appoint a commission of medical officers of the Marine-Hospital Service to investigate the origin and prevalence of leprosy in the United States and to report upon what legislation is necessary for the prevention of the spread of the disease. I have been unable to secure any information as to the practical outcome of the work of this Commission.

I need not remind this Association that the course of events within the last few years has given a new and added significance to the question of the control of leprosy in this country. At the meeting in 1894, a careful and competent observer, Dr. Hyde, in his report upon the distribution of leprosy in North America estimated that there was within our borders a leper population of from 90 to 150. There can be no doubt that Dr. Hyde's estimate was far too conservative as it has since transpired that there were in Louisiana alone more lepers than were embraced in his statistics for the entire country.

In the evolution of this country from a continental to a world power, its leper population has been largely augmented through territorial acquisitions. By the annexation of the Hawaiian Islands the United States has incorporated a native population tainted with leprosy. In absorbing Porto Rico and establishing a protectorate over Cuba our people have been brought into most intimate commercial and social relations with the leprous inhabitants of these islands. In appropriating the Philippines we have become possessed of one of the most important centers of leprosy in the Orient, and which, from its proximity to the "cradle of leprosy" in Kwan Tung and the leprosy-infected countries of Japan, must be continually exposed to fresh increments of infected material through immigration of Chinese and Japanese coolies.

That our territorial expansion has created conditions favorable to the increase of leprosy in this country cannot be gainsayed. The danger will come from the exposure of soldiers and sailors who form the army of occupation, of civilians who fill administrative posts in the government of these colonies, and others who are attracted by considerations of trade and commerce and who are thus brought into intimate contact with their leprous population. Whatever doubt there may be of the contagious activity of leprosy when transplanted to this country there can be no question of its ultra-contagiousness in these tropical islands.

It is worthy of note that the leper population of Southern and Central Europe within the present century has been almost entirely recruited from the ranks of soldiers and sailors or official representatives of the administrative departments who have sojourned for a longer or shorter period in leprous-infected colonies. Of the 100 cases of leprosy observed in Great Britain within

[1] Read before the American Dermatological Association at its annual meeting, held at Washington, D. C., May 1, 1900.

the past ten years, all, with possibly two exceptions, contracted the disease in the leper colonies of England. M. Olivade states that of the 1500 cases of leprosy in Spain, 500 of which had come under his personal observation, the great majority were soldiers or monks who contracted the disease in the Philippines, the Canaries or Cuba. The same authority traces the origin of the two most severe epidemic outbreaks of leprosy in Southern Europe within the past three centuries —*viz.*, the epidemics in the Provinces of Alicante and Parcent to the importation of the disease from the Philippines.

With these facts before us it may be pertinent to inquire how many of our soldiers who form the army of occupation in Cuba, Porto Rico and the Philippines will bring back leprosy as a souvenir of their sojourn in these islands.

There is another possible danger of the increase of leprosy growing out of the changed foreign relations of this country which may be briefly considered. The "open door" into China which has been proclaimed as one of the most conspicuous triumphs of American diplomacy has also its sinister aspect. The teeming population of China has always furnished a favorable culture field for many infectious diseases. The "Flowery Kingdom" has been the breeding-place and nursery of pestilential diseases, cholera, plague, as well as leprosy, from time immemorial. The "open door" will not only afford access to the rich products and trade advantages of the Celestial Empire but will also furnish an outlet to the pestilential diseases which have been domiciled there for centuries, but which have been comparatively isolated by the traditional exclusiveness of the people. There can be no commerce or free intercourse between nations or races without an interchange of infectious diseases as well as commercial commodities.

Further, it may be said, that the locomotive forces which modern progress has placed at the command of civilization—the rapid transit by sea and land—furnishing swift and frequent communication and facilitating free intercourse and intermingling of the people of different countries, may also serve as a means for the transportation and dissemination of infectious diseases. So that in the future it is probable that most infectious diseases will lose their endemic character and become pandemic. Witness for example the plague which, imported from its breeding-place in China into India four years ago, has not only ravaged that country but has spread over a large portion of the globe and threatens to become world-wide in its extension.

The only question is whether these Oriental diseases will survive the contact of civilization, whether the better stamina of our people, the improved personal and public hygiene and our modern methods of sanitary supervision will be sufficient to cope with and exterminate them.

Before dismissing this part of the subject it may be said that the Chinese have been the most active disseminators of leprosy in modern times. These pig-tailed Argonauts of the Orient in their world-wide migrations in quest of the Golden Dollar have invaded many lands and almost every land they have touched they have tainted with leprosy. Cantlie in his prize essay on leprosy (New Sydenham Society, 1897) brings forward abundant historical evidence to prove that the spread of leprosy in the Malay Peninsula, the Dutch, Spanish and Portuguese East Indies and in Oceanica, as well as in the Islands of Fiji, New Caledonia and Hawaii and the Western coast of America, may be traced to Chinese coolie immigrants. In this vast area he states that the spread of leprosy has been in all cases coincident and concurrent with the immigration and residence of the coolies.

The Chinese have been not only the chief contaminators but the chief victims. In all these countries it may be said that with the exception of New Caledonia and Hawaii, where the racial peculiarities and social customs of the natives have favored the propagation of the disease, the Chinese have formed the bulk of the lepers, in New York as in San Francisco, it is the Chinaman who is the dominant leper.

While it is not the object of this paper to consider the control of leprosy in our new colonial possessions, I have deemed it important to point out what may be termed *the pathological side* of our policy of expansion, because, in my opinion, no wise or comprehensive plan of prophylaxis for this country can be framed which does not take into account the increased influx of infective material from these new sources of supply.

The leprosy of the United States, with the exception of Louisiana, is largely a foreign product, ingrafted by immigration, and it is impossible to destroy the growth *within* our borders if it is continually nourished by transplantation from *without*.

The most obvious indication, then, is to suppress the sources of supply, as far as possible, by the exclusion of all leprous immigrants. I say as far as possible, because quarantine against leprosy, although a most excellent measure, is and must be, from the very nature of the disease, incomplete in its operation. No system of quarantine has ever been devised that will effectually prevent the importation of a disease so prolonged in its incubation and so little manifest on ordinary inspection as leprosy. The advanced cases may be detected and turned back, but the incipient cases will slip through, despite the most rigid quarantine *cordon* that can be established.

Quarantine protection could doubtless be made more effective by international cooperation between this and other governments in which leprosy prevails, and by the examination of immigrants at the port of embarkation. All immigrants coming from leprous families and from leprous-infected districts, even if they show no signs of the disease, should be registered and kept under surveillance for several years after their arrival in order to watch for developments. The good effect of such a system is shown in the

operation of the international regulations which apply to the importation of Japanese coolies into Hawaii. A thorough examination is made before the laborers leave their own country and also upon their arrival in Hawaii. Among the 26,000 Japanese laborers who have been brought to Hawaii under the operations of these laws only six cases of leprosy have developed.

A careful examination should be made of all returning soldiers or civilians who have sojourned for a long time in our own or foreign leper colonies. While citizens of our own country cannot be denied the right of entrance and asylum, the identification and proper disposition of all such cases are essential to the control of the disease. Not only a seaboard but an equally rigid land quarantine should be established upon our Mexican and Canadian borders.

Another measure of increased efficiency would be the employment of skilled experts as quarantine inspectors. It does not appear that any special knowledge or training in the diagnosis of skin diseases has ever been considered a necessary qualification in the appointment of medical inspectors, although the large proportion of quarantinable diseases are distinguished by their skin lesions.

We come now to a consideration of the control of leprosy *within* the United States. What is the situation? Some of the practical aspects of the leprosy problem, relating to the extent of the evil, the attitude of the public and our health authorities, and the indications which point to its development and spread, may be briefly referred to.

There are numerous known foci of leprosy in various parts of the United States with an indeterminate number of cases scattered throughout the country. The actual number of cases of leprosy in any country is an unknown and unknowable quantity. From the very nature of the disease statistics cannot be computed by the methods ordinarily employed for the detection and registration of disease. Leprosy is a disease which readily lends itself to concealment and, unfortunately, the strongest motive for concealment is furnished by the hostile attitude of society toward the leper, due largely to an exaggerated conception of the acute, infectious nature of the disease. Science teaches that a leper is quite as innocuous from the point of view of contagion as the consumptive in the ordinary relations of life, yet the leper is shunned and avoided as the bearer of a deadly contagion, while the presence of the consumptive creates no concern. The presence of a leper in any assemblage or public conveyance would, if known, cause the wildest consternation and alarm. An incident occurring in St. Louis a few years ago may be mentioned as an illustration. "On the occasion of a leper being brought into Court upon *habeas corpus* proceedings there was a stampede from the court-room, even the judicial ermine sharing in the flight."[1]

At the present day, in some parts of this country, the leper is as much of a pariah and an outcast as he was when stoned and driven forth from the walls of the city under the Levitical law. The badge of leprosy is to-day as shameful and degrading as it was in the medieval ages; although the leper is no longer compelled to wear upon his breast the red letter L. to distinguish him, he is none the less clothed in the scarlet cloak of infamy by public opinion. It is not surprising, then, that a disease which attaints not only the bearer, but also his family, rendering them outcasts from society, should be sedulously concealed.[1]

While there is no doubt that a public sentiment which leads to the avoidance of close contact or companionship with a leper, thus favoring his comparative isolation, is to a certain degree wholesome and protective, yet carried to such an exaggerated extent it is as senseless as it is to be deplored.

As regards the attitude of our health authorities it may be said that no organized or systematic effort has been made for the control of leprosy in the United States. Louisiana is the only State in the Union which has provided a special asylum or lazaretto for the reception and care of its leper population. Although the provisions of the act creating this institution make it obligatory that all persons in the State afflicted with the disease should be isolated therein, the policy of segregation has proven a comparative failure.

In a recent communication to me Dr. Dyer states: "The legislation as it stands is quite sufficient for all purposes, but it fails of efficacy for several reasons, *viz.*: (1) The Board is made up largely of laymen who have no conception of hospital necessities and who have fulfilled the law creating them only in so far as they have provided an asylum for such lepers as may choose or as may be persuaded to take refuge there. (2) The physicians of Louisiana are blind to the urgency of reporting cases of this disease or they, like myself, are unwilling to send any patient to the home to die without treatment of a disease which is amenable to medical care if not cure. It is my opinion that the question of leprosy control in Louisiana is as yet unsolved. During the existence of the leper-house there have been to my knowledge over 150 lepers at large while only about 30 have been in the home."

Although the health authorities of other States are empowered to isolate leprosy under the provisions of the general law applying to diseases dangerous to the public health, yet the exercise of this authority has been for the most part feeble and spasmodic. In some States repressive meas-

[1] In the presence of leprosy humanity ceases to be humane; even the mantle of Christian charity is not broad enough to cover this disease. In a little town in Ohio two children of a deceased Union soldier who had served in the Civil War were found to be affected with a rare form of disease, which experts who were consulted pronounced to be syringomyelia—the other six children in the family were unaffected. The dread word, *leprosy*, whispered abroad, was sufficient to transform the little circle of friends and neighbors into a hostile community. An impassable barrier was placed around this family by public sentiment. The children were denied school and church privileges and cut off from all communication with their fellows. The attending physician writes me, "they are as completely isolated as if shut up in a prison."

ures have been limited to the impounding in the nearest pest-house of any vagrant leper who might wander into a dispensary or be apprehended in the streets; in others a do-nothing policy has prevailed.

The Health Board of California has the power to confine in the pest-house of San Francisco all lepers found within the limits of the State; and the enforcement of the law, especially in the case of Chinese immigrants, has been more vigorous than in most other States.

Among the Eastern States Pennsylvania has perhaps waged the most relentless warfare against the leper; all known lepers coming under the jurisdiction of its Health Board have been imprisoned or deported and physicians fined for not reporting cases.[1]

The action of the municipal and State authorities of New York toward leprosy has been inconsistent and to a certain degree capricious. About ten years ago the Health Board of New York City began to take official cognizance of leprosy. All lepers coming within its jurisdiction were isolated on North Brothers Island, at first in a tent and later in a disused building for contagious diseases. Three years ago the lepers were allowed to escape and since then the disease has been practically ignored by the Health Board.

It must be confessed that the Health authorities of New York have been confused and hampered in pursuing a systematic policy by the conflicting and contradictory opinions of their medical advisers as to the contagious nature of the disease and its danger to the public health. It would be foreign to the scope of this paper to present arguments in favor of the contagiousness of leprosy —suffice it to say that the clinical evidence is overwhelming and conclusive. It will be admitted, however, that the virulence of leprous germs is modified by natural agencies, and that leprosy does not always and under all conditions comport itself as an actively contagious disease. So that a perfectly honest observer who limits his field of observation to certain favored regions will find little evidence of its contagious activity.

In New York City, for example, lepers coming from countries where the disease is endemic have lived for years. Many have been sent to the Charity Hospital where they have died, one having been employed as nurse, another as orderly in the institution and, so far as is known, no case of indigenous leprosy can be traced to association or contact with these patients. Again, of the 170 or more Norwegian lepers who have settled in New Scandinavia, there has been but one single case of contamination traced to contact with these imported lepers.

Too much stress has doubtless been placed on these negative facts of contagion. The same argument might be employed against the contagiousness of syphilis and tuberculosis. Thousands of consumptives and syphilitics have been treated in the Charity Hospital without communicating their disease. Besides the lepers in New York have been for the most part Chinese and West Indians who have been comparatively isolated by their color, race-prejudice, etc., and have not mingled freely with the general community. Neither is it surprising that the Norwegian immigrants have failed to propagate the disease, when we consider the conditions of their new environment. They settled in an open country, in new houses far removed from each other, with plenty of air and space about them and were thus comparatively isolated.

If we now turn our attention to Louisiana we shall find the most abundant evidences of contagion, as evinced by the notable and alarming increase of the disease and the large proportion of indigenous cases. The endemic outbreak in Louisiana is of extreme interest and importance, not only in illustrating the variable virulence of leprosy but also as affording an example of the remarkable decline and recrudescence of the disease under the same social and hygienic conditions. It also shows that the prolonged exemption of a community in which the seeds of leprosy have been implanted does not guarantee a continued or permanent immunity from the spread of the disease. The infection of a community with leprosy, like that of an individual, usually exhibits a prolonged incubatory phase. Twenty-five years ago not a half-dozen lepers could be found in the entire State and the disease was regarded as practically extinct—over 300 cases have been recorded since that time. What has happened in Louisiana may happen in New York or elsewhere.

My own impression is that leprosy is slowly gaining ground in this country. The fact that more cases have come under my observation within the past five years than in twenty years previous may, perhaps, count for nothing, but the fact that the records of the New York Dermatological Society embrace more cases within the past five years than in the twenty-six previous years of its existence is important as an indication of the increase of the disease. Another fact of significant import is that cases of indigenous leprosy are unquestionably multiplying. Two such cases were presented to the Society within the past few months.

From this survey of the subject we may conclude that there are many indications which point to the spread of leprosy in the United States, *viz.*: The new danger of infection to which this country is exposed from its political and commercial relations with its leprosy-infected colonies, the notable and alarming increase of the disease in Louisiana, and the evidences of its indigenous growth in that State and elsewhere. Our sanitary authorities should view this growing evil not with the apathy of indifference, nor yet with the overwrought apprehension that a dreadful revival

[1] I am informed by one of my colleagues that there may be found just outside the gates of the "City of Brotherly Love" a leper who has been confined in a disused dwelling, some distance removed from any other habitation, for seven years. During this period he has lived solitary and alone, his food being brought by an attendant who deposits it in a trough outside the door. And yet this glaring anachronism in sanitary control is perpetrated in the enlightened and progressive commonwealth of Pennsylvania.

of the medieval scourge threatens this country.

Assuming the urgent necessity of the control of leprosy in the United States we may now inquire whether this sanitary duty should be divided among local and State authorities or be centralized in the National Government.

It must be confessed that the policy pursued by our municipal and State boards of health in dealing with cases of leprosy coming within their jurisdiction is condemned by its results. It has consisted either in a resort to the harsh and cruel measure of imprisoning the leper in the nearest pest-house, or it has been a policy of inaction. There has been a lamentable failure in checking the evil and the experience of the past would seem to show that State control of leprosy is utterly impractical. Two causes may be assigned for this failure, one is the irregular distribution of the disease in the different States, the other is the expense and trouble involved in providing and maintaining separate buildings for the isolation and care of the lepers. It will be allowed that organized and concerted action is essential to any effective control of the disease, otherwise lepers living in a State where isolation was enforced would migrate to other localities where no such repressive measure was in force. The expense is considerable. Dr. Bracken states that he took occasion to inquire into the cost of maintaining two lepers in a township in Minnesota and found that it involved an expense of $1210 per annum with an addition of $1000 for a separate building. In some States there are but few known cases of the disease; in others none at all. It would be difficult to persuade the health authorities of a State in which there were perhaps but two or three lepers to assume the expense of providing a separate building for their isolation. The absence of any such provision leads the health authorities of many cities where leprosy is known to exist to conceal this fact from the general public.

For this and other reasons that might be referred to, the obvious conclusion is that the control of leprosy in this country should be committed to the National Government. The right of the Government to assume such control need not be discussed. The most ardent advocate of State rights would hardly oppose the good offices of the Government in relieving the State of the care of its lepers.

What are the most effective measures that can be employed for the suppression of leprosy? The consideration of this subject should be approached in a scientific spirit, divested of the medieval conception of the horror and virulence of the disease, and, at the same time, in a humane spirit—recognizing the leper as entitled, by reason of his affliction, to kind and charitable treatment. What are the methods by which this two-fold object—the protection of the public and the welfare of the leper—can be best fulfilled?

Isolation or segregation undoubtedly represents the most effective means known to sanitary science for the control of this and other contagious diseases. For the practical enforcement of this sanitary scheme the cooperation of the profession in reporting all cases of leprosy coming under their personal observation is, of course, essential. But to report a case of leprosy with the certain knowledge that the patient would be promptly immured in a pest-house, or confined like a criminal is abhorrent to every sentiment of humanity. Until proper provision is made for the care and medical treatment of lepers there can be no cordial cooperation on the part of the profession.

Another aspect of this question is worthy of consideration. Few physicians in this country are familiar with the clinical aspects of this disease and, therefore, are not competent to make a diagnosis. Now, the diagnosis of leprosy carries with it a grave responsibility which should not be lightly weighed. The isolation of all other contagious diseases contemplates brevity. To a smallpox patient, isolation means a few weeks' separation from his family and friends and a temporary interruption of his business, but for the leper it means an absolute and permanent severance of all his worldly interests and relations and life-long confinement. The consequences of a mistaken diagnosis are of such vital import that to prevent such a miscarriage a board of competent experts selected for their skill in the diagnosis of the disease should be appointed, and the verdict of leprosy should never be pronounced or, at least, accepted as final unless confirmed by such an examining board. Cases in which the symptoms are suspicious but not absolutely positive should be re-examined from time to time until they either clear up or become conclusive.

An intelligent discrimination should be exercised in the selection of cases suitable for segregation. I am not prepared to subscribe to the dictum "that every leper whenever and wherever found should be summarily seized under Government edict and confined until he dies," nor to the report of the Committee of the American Medical Association that "the enforcement of compulsory segregation should be absolute and implacable." A spirit of persecution, breathing out "threatenings and slaughter," has no place in the counsels of enlightened sanitary science. It is to be condemned on the ground of humanity as well as a matter of policy. The experience of all countries shows that it defeats the object in view by leading to the concealment of cases.

The highest wisdom of sanitary science is shown, not merely in the isolation of contagious diseases, but in a knowledge of the special conditions under which the contagion of each particular disease operates and the adaptation of the sanitary measures employed for its control to meet these conditions. The contagious mode of leprosy is not like that of an acute infectious disease—smallpox for example—but rather like that of tuberculosis or syphilis, depending upon the form and stage of the disease, the conditions of contact, etc.

If these conditions are absent or can be controlled in the case of the individual leper, there

is no risk of contamination. I do not, therefore, believe that every leper found in the United States should be subject to compulsory segregation, irrespective of the form and stage of the disease and of his social and material circumstances. There would seem to be no reason to fear that an anesthetic leper in whom the bacilli are few and deeply lodged in the nerves with no chance of their elimination through broken or ulcerated surfaces in the nose or elsewhere will communicate his disease. If his material circumstances are such that he can live by himself under proper surveillance, provided with a separate room, bed, board, etc., and does not come in intimate contact with others, he is practically innocuous. In cases where such conditions cannot be complied with, the leper should be placed in an asylum especially provided for this class of patients.

My own views of such institutions were expressed in a recent article on leprosy (Twentieth Century Practice of Medicine). "Home or asylums with suitable hygienic surroundings should be provided for the care and maintenance of lepers by the National Government. Such asylums should be made comfortable and attractive and arranged with special adaptation to the requirements and peculiar needs of its inmates. In view of the chronicity of the disease lepers should not be condemned to close confinement and inactivity but should be provided with interests, means of employment and recreation. As a large proportion of lepers are able to engage in some kind of industry such institutions might be made partly or wholly self-sustaining from the proceeds of their industries. They might be conducted as colonies and provision should be made for giving occupation to those able to work. Many lepers would doubtless avail themselves of such an institution without compulsion. There comes a times in the history of every leper when he would be glad of any asylum to end a miserable existence. Again there are many lepers who would voluntarily go to such a refuge as soon as the nature of the disease is evident for fear of spreading the contagion to their family or friends."

The inmates of such institutions should be provided with proper medical care. There is no doubt that if sanatoria or colonies were instituted for the reception of lepers, as in the case of consumptives, and provided with suitable means of treatment in the earlier stages, many of the cases might be aborted or the progress of the disease arrested.

Twenty-five years ago tuberculosis was classed as an incurable disease. Under the rational treatment employed at the present day the statistics of some of our sanatoria show 25 per cent. of cures and a still larger percentage of arrests of the disease. Such brilliant results are, of course, more marked in incipient cases. The doleful statistics of leper hospitals are based almost exclusively upon the treatment of advanced cases, as incipient cases rarely enter. There can be no doubt that the lamentable failure of our therapeutic measures against leprosy is due largely to the conditions under which they have been applied. The dominant conviction forced upon a leper when placed in a lazaretto is that he is shut up to die and the utter hopelessness thus engendered renders all treatment a failure.

A qualified expert with all the modern appliances for scientific investigation should be connected with each colony. The collection of lepers would afford an admirable opportunity for the study of the disease from a scientific standpoint. In countries where leprosy has most prevailed there have been few physicians fitted by scientific training or equipped with modern instruments of precision for the prosecution of bacteriological research. Among the unsolved problems of leprosy those relating to the life conditions of the bacillus and the modes of its propagation are most important in relation to the prevention of the disease.

Finally, it may be said that segregation, although a most valuable measure in the suppression of leprosy, has always proven in countries where it has been tried a defective measure, as its thorough enforcement has been found impossible. No official drag-net can be constructed which will gather in all the lepers in any country or community. The chief causes of failure must be sought for, as already pointed out, in the attitude of society toward the leper and the punitive character of the methods employed. Lepers in good social circumstances have assured me that they felt the dishonor of the disease to be its most fearful feature. It is not surprising, therefore, that all incriminating evidences of a disease which public opinion brands with the stigma of odium and disgrace and which condemns the bearer to the same punishment that is meted out crime, should be concealed as long as possible.

One condition which would promote the success of segregation is the removal of the popular prejudice and insensate fear of the disease which, deeply-rooted in the ignorance and traditions of the past, still survive at the present day. The medical profession in their capacity of teachers as well as guardians of the public health should enlighten the public upon these points. Not only the public mind but the public conscience should be educated, so that the spirit of proscription and persecution which society has in all ages exhibited toward the victims of this disease should be supplanted by a spirit of tolerance, if not of sympathy for their unfortunate lot.

It will be admitted that there is need of a reform in the methods of dealing with the leprosy in this country both in the interest of the public health and the welfare of those afflicted. The policy of inaction, no less than the policy of penal infliction should give place to a wise, comprehensive and energetic system of segregation which should be carried out with humanity and an intelligent discrimination. Instead of the traditional lazaretto, with its veiled inscription "All hope abandon, ye who enter here," asylums

should be provided which should be suggestive in their surroundings and mode of management of a sanatorium rather than a prison. These institutions should hold out assurances of humane care, of medical treatment, and, if possible, a hope of cure.

CAUSATION AND RELATIVE FREQUENCY OF TYPHLITIS, PERITYPHLITIS AND APPENDICITIS IN INFANCY AND CHILDHOOD.[1]

BY JOSEPH HENRY BYRNE, M.D.,
OF NEW YORK;
VISITING SURGEON TO THE METROPOLITAN HOSPITAL AND DISPENSARY.

PATIENT research and our advanced pathological knowledge have cleared up many an obscurity and forced us to disregard many a theory that only a few years since appeared tenable. Grisolle about 1839 did his best to controvert the teachings of Albers, which he correctly perceived were erroneous, but owing to the support of Dupeytren, Ferrall, Laennac and others equally as prominent, his views were completely lost sight of for nearly fifty years. He claimed that inflammations of the cecum were not accompanied by productions of pus and perforations of the appendix and pointed out that dysentery and ulceration of this part had no tendency to involve the adjacent connective tissue, but that disease of vermiform appendix with its phlegmonous inflammation, pus formation and perforations, explained satisfactorily the chain of events as we now know them to take place. The weight of evidence is so great that it must now be apparent to all that inflammation of the cecum takes little or no part in the production of appendicitis, that few cases of typhlitis exist as a primary disease, and that perityphlitis only occurs as a secondary complication. The cecal theory is now a thing of the past, as all clinical and pathological evidence is opposed to it. Renvers in 586 autopsies after perityphlitis found the appendix ruptured in 497 cases. Agar in 218 similar cases found the cecum ruptured only 29 times, but does not state whether this took place from without inwards or in the opposite direction. It is well known that inflammation of the large and small bowel has little or no tendency to involve the peritoneum and that the opposite is the rule with the inflamed appendix. With this in mind it is easy to understand how the inflammatory process can extend to the serous coat of the neighboring parts and the adjacent connective tissue. As careful an observer as Talemon states that early operation seldom or never shows that the cecum is involved (by inflammation or perforation), but admits that it may become the seat of trouble which, however, is secondary to disease of the appendix, not including those cases of tuberculosis, dysentery and typhoid. Stercoral accumulation in the cecum may occasionally produce a mild inflammation but never give rise to ulceration and easily disappear upon the administration of purgatives.

The inner coat of the gastro-intestinal tract is frequently the seat of varying degrees of inflammation in infancy and childhood, and more especially during the warmer months. Therefore, if these ordinary inflammatory processes took a prominent part in the production of appendicitis, this disease would be more frequently met with during the summer season, but such is not the case. Statistics prove beyond a question that this trouble is rather infrequent before the fourth year, increasing between that and the tenth, and that the majority occur between the latter and the thirtieth year. I have yet to see in my fifteen years' experience a case of primary typhlitis or perityphlitis, and as the literature of recent years shows the experience of others to be somewhat similar, my paper, therefore, resolves itself into one on appendicitis.

The appendix varies more in *size*, position and general make up than all the other structures of the human anatomy. In the early periods of life it is very rich in lymphoid tissue and has been styled the tonsil of the intestines. The size bears no relation to the frequency of the disease. The organ being a functionless, atrophied and rudimentary one, with a blood-supply that can easily be interfered with and which under healthful conditions seems barely sufficient, it must, therefore, be more or less susceptible on account of its low degree of vitality to inflammatory disturbances. The physiologist assigns to it no special function or even an indirect part in our vital economy.

The credit for our present knowledge belongs to us owing to the excellent work of Weir and McBurney of New York, Fitz of Boston, and Hodenpyl of this city, who, by the way, was the first to suggest that the bacillus coli communis played an important part in the production of the disease.

Etiology.—The presence of foreign bodies is now looked upon as a minor factor in producing appendicitis, but when they do exist they, like concretions, act in a mechanical way. When the mesentery is long the appendix is likely to assume a position that is almost straight, but when it is incomplete it may become curved or twisted, thus interfering with the circulation and also with the free drainage of the normal secretion preventing the egress of any fecal matter that might enter favoring the formation of concretions. The appendix is not at all exclusive in the choice of position and in about 60 per cent. of the cases the site selected favors gravity and facilitates free drainage, but when the position is a pendent one the ingress of matter is aided while the egress is hampered, thus inviting the formation of concretions. The cavity of the appendix and the opening into the cecum often predispose to inflammation: previous attacks of disease, or retrograde metamorphosis, having resulted in a narrowing of the latter or the production of one or more strictures of the lumen. Strictures are very frequent between the first and fifteenth

[1] Author's abstract of paper read before the Section on Pediatrics of the American Medical Association, Atlantic City, June 5-8, 1900.

year and the question as to whether these lesions are pathological or the natural consequence of retrograde changes is not yet satisfactorily decided. They have been found a number of times in the fetus and also in the new-born.

Relatively the appendix is larger in fetal life, infancy and childhood than it is in the adult, and compares to the large bowel as 1:10 while in the latter it is 1:20. It is also somewhat longer and wider in the male than in the female and this holds good in early life. It reaches its maximum size between the tenth and twentieth year and from here on it remains at a standstill or diminishes. This diminishing ratio is nothing more than a physiological or pathological retrogression, and with it goes a decreasing vascularity, and as the tissues receive their nourishment through the blood, I am therefore firmly convinced that the slight immunity that exists in early life can be credited to the fact that these changes in the majority of cases are not sufficient to interfere with the integrity of the part until after the fifteenth year and statistics support this assumption as only 15 per cent. of all cases of appendicitis occur prior to the fifteenth year. The female, both young and old, is less frequently the victim of appendicitis than the male. The comparatively smaller size of the organ with its increased vascularity (an anastomotic branch being given off from the region of the right ovary) accounts for this slight immunity.

One attack of appendicitis predisposes to subsequent inflammations, and this may be brought about either by a constriction, adhesive bands, the presence of a concretion or interference with the circulation. Constipation or diarrhea, if at all, are only minor etiological factors. If, as Maicaigne states, the bacillus coli communis of diarrheal discharges is much more virulent than it is in the healthy bowel, diarrhea may then become a more active agent. Any inflammatory state in this region may at times result in an appendicitis, especially if one or more of the predisposing conditions exist, owing to the fact that the appendix is less capable of resistance on account of its diminished vitality.

In early life the mucous membrane of the appendix possesses wonderful power of absorption and this in itself may become an active predisposing cause.

Exposure is a possible element in the causation of the disease. Several instances have been recorded, but none during infancy or childhood so far as I have observed.

Typhoid and tubercular ulcers of the appendix are met with post-mortem, but are seldom seen after operation. When the solitary glands of this organ are involved during an attack of the former disease the process of healing may result in the formation of a constriction and thus this disease may become a factor in bringing about this affection. Micro-organisms are now looked upon as being active exciting agents, and the bacillus coli communis is the germ most frequently found. Hodenpyl notes its presence in 34 out of 35 cases, Hawkins in 57 out of 61, and others give like experience. They may act independently, but their invasion is usually secondary to some existing condition. Welsh states that the bacillus coli communis is innocent if the integrity of the mucous membrane is maintained, but becomes pathogenic when the same is inflamed or injured. Hodenpyl, however, found numerous bacilli in the walls of the appendix without any lesion of the membrane.

Traumatism as a cause of appendicitis may be of two kinds. Direct and indirect. Instances of the former are matters of record and while it is possible for indirect violence to become an etiological factor, I feel positive that the appendix is already in a receptive state, and, therefore, while the injury may seem to be the active agent, it is only a minor factor in the causation of the trouble. Foreign bodies and concretions, when they exist, no doubt play an important rôle. The former may become a nucleus for the latter which are always formed in the appendix, but they both occur less frequently than was formerly supposed. When they do exist they act as irritants to the mucous membrane, producing a catarrhal inflammation and facilitating the invasion of micro-organisms and, secondly, by mechanical interference, occluding the lumen, acting as a ball-valve at the opening itself, or the seat of the stricture obstructing the circulation even so far as producing gangrene, and, finally, by pressure.

Expression of a Concretion by Digital Manipulation.—On April 15, 1900, I was called to see a boy who had been suffering from constipation for five or six days. Two days prior to my visit, on forcing a movement, he was taken with pain about the umbilicus which continued at irregular intervals. On the morning of the 15th he was seized with severe vomiting, the pain increasing so as to produce syncope. When I saw him he was on his side with the thighs flexed and stated that this was the most comfortable position. His temperature was 101° F., pulse 114, and he complained of continuous pain with frequent severe spasmodic seizures, which caused him to cry out. The abdominal wall was exceedingly thin; muscular resistance was not marked. I was, therefore, able to make out the appendix with comparative ease and found it in a state of erection and in a somewhat unusual location, directed upward and outward toward the crest of the ilium. The appendix I judged to be about three inches long and about one inch from its distal end I discovered a small but hardened fecal mass which I pressed toward the gut. On the following day his condition was about the same, but I was unable to make out the appendix owing to muscular resistance. I suggested operation but the father preferred waiting until the following morning, when to my surprise the boy had greatly improved, the temperature being normal, and the pulse 84. No pain, tenderness greatly diminished: the appendix could be felt but the concretion was no longer in evidence. He complained of extreme hunger and stated that he was en-

tirely well. Case passed out of my hands on the nineteenth as the parents considered a recurrence the main indication for an operation.

The expression of hardened fecal masses by digital manipulation to my knowledge has never before been referred to, and although the cases in which this mode of procedure would be applicable must necessarily be few, I could not refrain from directing attention to the manner in which this very satisfactory result was accomplished.

PERIODS IN GYNECOLOGY.[1]

BY HENRY J. GARRIGUES, A.M., M.D.,
OF NEW YORK;
CONSULTING OBSTETRIC SURGEON TO MATERNITY HOSPITAL, VISITING GYNECOLOGIST TO ST. MARK'S HOSPITAL, ETC.

FIRST of all I wish to express my deep-felt appreciation of the honor you have conferred upon me by offering me the opportunity of reading a paper before you. The temptation to accept your kind invitation was so great that I could not resist it, although I know how great a risk I run in assuming the appearance of having anything to offer that you do not know and perhaps practise better than I. But when the hair turns gray and the body begins to shrink, one has reminiscences that may, at least for a moment, entertain the younger men who listen to him.

More than a quarter of a century has elapsed since I began to pay special attention to gynecology. I was then in my native country, Denmark, and gynecology was just beginning to find its way as a specialty to our shores. America was very far off at that time; still, before making it my home, I was quite familiar with the work of Marion Sims, Thomas Addis Emmet, Washington L. Atlee, and Theodore Gaillard Thomas. At that time London was the chief center to which flocked the greatest European surgeons, a Nélaton, a Billroth and a host of rising men, to learn ovariotomy from the man who had had the courage to take up again this American operation when, on account of the large mortality following in its wake, it had fallen into discredit in England. It was, then, a wonderful advancement when Thomas Spencer Wells reduced the mortality to 25 per cent. I had the advantage in 1872 to see nine ovariotomies performed by the master of the day. Although the antiseptic treatment of wounds by Joseph Lister had already been introduced at least seven years previously at Glasgow, it had hardly been adopted anywhere except in Copenhagen.

In those days the chief point of interest was how the pedicle should be treated. Baker Brown had severed it by compression and cauterization; I saw Alfred Meadows tie it with whip-cord and drop it; Spencer Wells still clung to compression by means of a clamp and the extraperitoneal fixation in the abdominal wound. Soon the energies of the whole medical world were turned to this grand operation. Its period of evolution has ended long ago. Perfection has been reached in the technic and mortality in experienced hands has been reduced from 25 to 2½ per cent. Unfortunately *pari passu* with this development has gone a greatly diminished need for the operation; since ovaries, with or without cause, were so frequently removed while small, they did not have time to form large tumors, so that ovariotomy nowadays has become one of the rarer gynecological operations.

When one examines the titles of articles on gynecological subjects in their chronological order, one is reminded of the geological layers superimposed one upon another in the crust of the earth. In those years nearly the whole interest was concentrated on ovariotomy, while nowadays we hardly ever meet with an article on this subject, on which, at least for the time being, the last word seems to have been said.

Then there came a period when the treatment of the cervix for stenosis or flexion and the concomitant dysmenorrhea and sterility was the absorbing topic. We had long discussions about incision and discission, and later, for a time, both were discarded for dilatation under the leadership of your late townsman, William Goodell. Incision, thanks to asepsis, having become safe, many, and I among them, have again returned to the more effective cutting operation.

The period of trachelotomy was followed by Emmet's operation for laceration of the cervix. In the transitional period before trachelorrhaphy was generally adopted, the scoffers had a good time, saying that one-half of the gynecologists were busy incising the cervix and the other half in sewing it up.

A little later curettage, one of the oldest gynecological operations, came into vogue. It has held its sway ever since and is at present, in my opinion, in that period of abuse through which it seems inevitable that every useful operation must pass. The general practitioner, who, in most cases, is not capable of making even a gynecological diagnosis, is very apt to put in a pessary or scrape out the womb, often with the result of starting a serious pelvic inflammation which may end in death.

With the year 1872 there came a new era in gynecology. Within the short period of a year the novel operation of removal of the uterine appendages was done by three men with different aims. Hegar in Germany did it in order to produce premature menopause in cases of bleeding uterine myomata. Robert Battey of Rome, Ga., performed almost simultaneously his so-called "normal ovariotomy" for serious nervous affections, the starting-point of which he took to be in the ovaries. Before either of these surgeons, Lawson Tait of Birmingham had extirpated the ovaries and tubes for diseased conditions in these organs themselves. Thus, attention was called to the tubes as an important seat of disease, and "Tait's operation" became the chief gynecological procedure during the next score of years. This was also grossly abused, entirely normal

[1] Read by invitation before the Section on Gynecology of the College of Physicians of Philadelphia.

ovaries being passed round in medical societies as trophies, until a more conservative spirit taught us that even diseased tubes and ovaries need not necessarily be removed, but might often be cured by medical means, electricity or conservative operations.

During the same period considerable attention was paid to the repair of the torn perineum. Often it was only a desire to do something new that gave rise to slight modifications of old methods; but within the last few years real progress has been made, and one of these new modes of treatment is due to a member of this Section, Dr. Barton Cook Hirst.

Besides perineorrhaphy, displacements of the uterus are receiving considerable attention in our time. Alexander's operation not only holds its own but is spreading. In uncomplicated cases of retroversion or retroflexion it is my favorite operation. It seems to me that with so simple a means of relief at our command, we are not justified in performing laparotomy for conditions, which, although they may give rise to considerable suffering, never threaten the patient's life. For a time many were opposed to this operation because they failed to find the ligaments at the external inguinal ring. It has been stated by good observers that the ligament may not exist, but this is certainly so rare a condition that it may be left out of consideration. With the exception of my first operation of this kind, which was performed on an old woman on whom it ought not to have been attempted, I have found the ligament in every case. A more serious objection is that some operators have stated that the uterus, after the operation, returned to its faulty position. Here, again, I am inclined to think the fault was in the operator and not in the operation. I have reason to believe that some operators overlook the rule of Alexander, that the operation should be combined with the temporary use of pessaries. He lays so much stress on this point that he declares that if no pessary is used it is no longer his operation. If there is a retroflexion he insists on having an intra-uterine stem inserted and kept in for two weeks, and under all circumstances, the patient should wear a Hodge pessary for at least six months. Since the operation is often performed on virgins or combined with colpoperineorrhaphy, I have had special long, narrow vaginal pessaries made for the purpose of taking the strain away from the place in which the round ligaments have been fastened, without undue stretching of the entrance to the vagina. I have seen several of my patients upon whom I had performed Alexander's operation after they, in the meantime, had borne a child. There had been no trouble during pregnancy and delivery, and the uterus was found in an entirely normal position.

I do not deny that similar results may be obtained either by fastening the round ligaments to the vagina or by shortening them through this organ, but these operations are comparatively difficult and not altogether free from danger, while Alexander's operation for one familiar with the anatomy and technic, is simplicity itself. If well performed the abdomen does not even show a scar after the operation. By taking care not to extend the incision beyond the portion covered with hair, the lineal cicatrices will be entirely concealed when the new growth appears.

The chief subject of discussion in our time is, however, hysterectomy, and I think it is fast approaching the same settled condition of perfection that ovariotomy obtained long ago. In this respect the year 1890 marks the beginning of as distinct a period as did the year 1872 in regard to salpingo-oöphorectomy. In 1890 Péan laid before the International Medical Congress, assembled at Berlin, a report of fifty cases of pelvic pus collections, treated with vaginal hysterectomy by means of clamps. At that time the operation was only recommended for large, bilateral abscesses, but soon the method of entering the abdominal cavity from below was applied to nearly every morbid condition in the pelvic organs. Before Péan—leaving out of consideration a few isolated operations by surgeons of another age—this route was used by Robert Battey in normal ovariotomy and by Carl Schroeder in the extirpation of the cancerous uterus. But since Péan's paper vaginal section became so popular that to a great extent it replaced laparotomy. One of the reviewers of the second edition of my text-book on diseases of women, I believe a gynecologist of this city, reproached me for having placed vaginal section on an equal footing with the abdominal method. If he is here to-night, I wish to explain that, as an author of a text-book, it is my duty to reflect what is being done and what, by many, is believed to be the best treatment. I may at most expose the advantages and drawbacks of different methods, and I have done so frankly and distinctly. Viewed from the standpoint of the practical gynecologist, the situation is very different. In the choice of an operation I give due consideration to the following points, first, which method is preferable in itself; secondly, which is most appropriate in the given case; and finally, which I can do best. As I stated above, that for retroflexion and retroversion I preferred the extraperitoneal shortening of the round ligaments to all other methods of treatment, I may now say that, with few exceptions, I prefer the abdominal to the vaginal section. The exceptions are a uterus with beginning carcinoma or sarcoma, not involving the parametria or the broad ligaments; a myomatous uterus, not exceeding the size of the first; and pelvic abscesses in the broader sense of the word—that is to say, any purulent collection which I can reach by colpotomy and perforation. In nearly all other cases I enter the abdominal cavity from above.

Much stress has been laid by the advocates of the vaginal route on the unsightliness of the scar left by laparotomy, to which I answer that the cicatrix is found in a part of the body that is hardly ever exposed to view, and secondly, that

if the abdomen is closed with care, and suppuration avoided by following the rules of antiseptic and aseptic surgery, the scar may be reduced to a narrow, straight, white line. A more serious impeachment of the abdominal section is that, on account of the length of the incision, it is more liable to give rise to the formation of hernia, than the vaginal section. But here again the surgeon can do much to prevent this untoward result by taking care to close the wound well.

There is less shock in the vaginal operation, since the intestines are hardly handled at all. The patient need not stay so long in bed. Pus may be evacuated without contaminating the abdominal cavity. A cancerous uterus may be removed without sowing germs on unaffected parts. On the other hand, the vaginal operation, on account of the small dimensions of the field, is more difficult to perform. We have to work at the bottom of a long, narrow tube. Without specula and retractors we cannot see anything, and when we use them they are often in the way of our fingers. Adhesions are more difficult to separate or cannot be reached at all. Hemorrhage is more difficult to check. The bladder and the intestines are more exposed to injury, and if such an accident occurs it is more difficult, or, perhaps, impossible to repair the lesion. The pelvis cannot be explored so easily and the abdomen still less.

The abdominal section offers the immense advantage that we can enlarge our incision *ad libitum*. Every part of the abdominal and pelvic cavities can be made accessible to view and touch, a feature of the greatest importance in these deep-seated affections in which the diagnosis of the most skillful often is uncertain or erroneous. When we have to deal with large, solid tumors there is no choice; but with small tumors, with some cases of ectopic gestation, and with inflammatory conditions, both routes are available, and the operator should choose the one which is most appropriate or which he can best perform.

Choosing the operation which has attracted the greatest attention in our period, I shall now describe an abdominal hysterectomy in every detail as I perform it, at the same time opening perspectives which will offer every one present, who feels so inclined, an opportunity to criticise me and speak in favor of other methods than those followed by me.

The patient is prepared for the operation by giving her a full bath and scrubbing her all over with soap, in order to have her skin in as good a condition as possible. The bowels are moved by means of compound licorice powder or sodium sulphate and furthermore emptied by administering a soap-suds enema, not later than six hours before the appointed time for the operation, as otherwise an evacuation is apt to take place during its performance. The abdomen is covered for twelve hours with a towel smeared with potassa soap, followed for a similar length of time by another towel wrung out of a solution of bichloride of mercury, 1-2000. At the time of the operation these antiseptic measures are supplemented by scrubbing the vagina with tincture of green soap and irrigating it with bichloride solution and lysol, which latter restores the smoothness lost by the use of the corrosive sublimate. Next, the abdomen is disinfected in a similar way, finishing off with alcohol.

I disinfect my hands with soap, hot water, bichloride of mercury, lysol, and alcohol. I do not use any gloves. Cotton gloves seem to me to be nugatory when we take the comparative size of their meshes and that of a microbe into consideration, and rubber gloves diminish my sense of touch and delicacy of manipulation so much that I think that on my hands they would do more harm than good. Besides that, we have sometimes pelvic operations in which we have to work in the dark with a perforator. In sliding the instrument along the index-finger, I have found that it is caught by the rubber and either folds it so as to be held back or tears it.

Before attacking the abdomen, the uterus is curetted and washed out, preferably with creolin on account of its hemostatic and antiseptic properties. In making the incision, two different scalpels are used, the first serving only to sever the skin. The *raison d'être* of this latest improvement is that the deepest portions of the cutaneous glands serve as habitat for pathogenic microbes which cannot be dislodged or killed by any applications to the epidermis. The knife that cuts through the deeper layer of the skin can, therefore, no longer be looked upon as aseptic, and it is a simple, but rational, precaution before proceeding any farther to exchange it for another.

The incision in the median line is best made from below upward on account of the direction of the fibers of the pyramidalis muscle. If there is a large tumor, we should bear in mind that the abdominal wall is thinned and under considerable tension. I have seen a gynecologist of large experience, overlooking this anatomical disposition, carry the first incision from the symphysis to the umbilicus through the whole abdominal wall and the omentum into a fibroid uterus, causing considerable hemorrhage and trouble in tying numerous vessels. It is not necessary to use any director, but the different layers of the abdominal wall should be severed one by one—the skin, the subcutaneous adipose tissue, the fascia, and the aponeurosis of the flat abdominal muscles. So far there is no danger, whereas the preperitoneal fat should be torn deliberately, and, finally, a small opening made in the peritoneum, lifting it well up and holding the scalpel almost horizontally, so as to expose the underlying omentum or intestine to the smallest possible danger. In one of my cases I found the unique condition of a fetal bladder extending all the way up to the umbilicus, between the aponeurosis and peritoneum. A bold incision would have led to an unnecessary lesion of this viscus, whereas by progressing slowly I saw the unexpected condition, dissected the bladder loose from its surroundings and dropped it into the pelvis before opening the peritoneal cavity.

The incision should be long enough to allow a perfect inspection and handling of all organs down to the bottom of the pelvis; but, on the other hand, it should not be longer than needed, because every inch increases the danger of the formation of a ventral hernia. It is preferable not to make it longer than three or four inches to begin with and after the peritoneal cavity has been opened to extend the incision upward as far as needed and downward as far as the bladder will allow.

When the uterus is exposed, it should be lifted up, for which purpose I have found the traction-forceps invented by Dr. B. F. Baer, of this city, most excellent. I begin by tying the ovarian vessels—veins and arteries—in the infundibulopelvic ligament on one side. If there are any complications the easiest side should be chosen. These vessels run at quite a little distance below the free border of the ligament. There is, therefore, plenty of room for passing the ligature twice through the ligament, which is better than to simply tie it over the free border, as in the latter case it may slip off. As a further precaution, it is well to seize the artery separately on the cut surface and tie it with medium sized catgut. Before severing the tissue, a clamp is placed between the ligature and the appendages.

Next, the round ligament is treated in the same way, and the first incision in the broad ligament extended so as to sever it. After that, a transverse incision is carried from the point where the round ligament has been cut, about a finger-breadth above the bottom of the uterovesical pouch to the corresponding point on the other side. This incision is quite superficial, so as to implicate only the peritoneum and the superficial muscular layer of the uterus. With closed scissors, finger-nails and an occasional nick with scissors or knife, the bladder is separated from the cervix. The uterine artery on the first side is now surrounded by a medium-sized catgut ligature, a clamp put between it and the uterus, and the original incision in the broad ligament extended down into the parametrium. Often this artery may be felt before applying the ligature to it; if not, the ligature is placed where the artery normally runs, near the edge of the uterus. As a rule, we shall secure it in this way; but if we cut it, no harm is done. It is simply seized and tied separately. Dr. Nicholas Senn does not even pay any attention to either uterine artery before it spurts. The first uterine artery having been secured, a transverse incision is made through the cervix where it joins the body of the uterus. It is stated by some operators that after turning the uterus well over to the other side, they see the second uterine artery running plainly at the bottom of the wound. I must confess that I have not been so fortunate. I tie it just as the first, guided by touch or, if even that fails me, by anatomical knowledge. The second uterine artery having been secured in one way or another, the second round ligament is tied and cut and, finally, the second infundibulopelvic ligament, and the uterus is taken out in one piece with both its sets of appendages.

Now we return to the stump of the uterus. If we want to perform supravaginal amputation, which is preferable when the cervix is healthy, we only hollow the surface out by cutting out a small piece from the top surface, disinfect the cervical canal with a few drops of carbolic acid, and bring the edges of the muscular tissue together with a few interrupted catgut sutures. Last of all, the two edges of the peritoneum are united by means of a running suture from one infundibulopelvic ligament to the other.

If a total extirpation is preferred, the stump is seized with a traction-forceps, pulled up and loosened from its surroundings, chiefly with closed scissors. The vagina is opened immediately below the cervical portion and severed all around. Some additional ligatures are needed on arteries coming from the vagina and the neighboring tissues. When the stump of the cervix has been removed, the edges of the vagina are stitched together, and then the peritoneum is closed over it, or, if preferred, the peritoneum is stitched to the vaginal edge and the hole packed with iodoform gauze. I use exclusively catgut that has been sterilized with formalin or boiled in alcohol under high pressure. By avoiding silk, we are guarded against the formation of fistulous tracts leading to a suture and slow to heal.

Dr. Senn advocates a modified extraperitoneal treatment of the pedicle, and Dr. Joseph Eastman is enthusiastic about a complete enucleation of the muscular tissue of the uterus, only leaving the peritoneal shell, both of which methods seem to me to be inferior to the one I have just described. Senn's operation takes much more time and requires two sittings. Eastman's is very tedious and nothing is gained by it, and as for peeling off the peritoneum, in my opinion it is impossible. The peritoneum of the normal and common myomatous uterus adheres closely to the underlying muscular tissue of the body of the uterus, so much so that Eastman has felt driven to construct a special pair of scissors, with little bulbs at the ends, in order to dissect it off. I believe that what he dissects off is not the peritoneum alone, but combined with a layer of muscular tissue. I have satisfied myself by microscopical examination that the muscle-cells of the uterus extend all the way out to the exceedingly thin endothelial layer forming the cover of that organ. Toward the end of pregnancy the connection between the peritoneum and the muscular tissue becomes considerably looser. In performing Cæsarean section, we see it lie like a mantle over the emptied uterus, easy to move and fold. But even in the pregnant condition the connection between the peritoneum and the muscular tissue is much denser on the fundus and the upper part of the body than on the lower uterine segment.

In a case I operated on recently for myomatous degeneration in a non-pregnant woman, I found,

however, the peritoneum so loosely adherent that it could be lifted up between the fingers an inch from the muscular coat. It had also a different color, being white and dull, instead of presenting the usual shining pink surface. It could with the greatest facility be torn off, like the broad ligament, from an intraligamentous tumor. But this is a unique condition. I have at least never seen it before, either in my own work or that of others. It is a similar condition to that known as dermatolysis, in which the derma contains so many elastic fibers that it can be pulled out everywhere to a great length like a sheet of rubber.

I take great care in closing the abdominal wound. First, I unite the peritoneal edges with a running catgut suture, then I unite the aponeurosis by means of chromicised catgut, using the cobbler's stitch, which takes a little more time than an overhand suture, but which is done with comparative ease with Marcy's needle. Finally, I unite the skin and subcutaneous fat with silkwormgut sutures, one inch apart, and place a superficial silk suture in the middle between each two and near the ends. For a time I tried Marcy's subcuticular suture, but had trouble with it and returned to the old way, which gives me a beautiful linear union, without showing any stitches.

When the aponeurosis is united, I like to wash the entire wound with a solution of bichloride of mercury. It cannot do any harm, and it appears to me as being conducive to primary union. After closing the wound, I dust it with eka-iodoform, cover it with iodoform gauze and apply a piece of guttapercha tissue, which sticks to the skin and forms a hermetical protection for the wound. Outside of that come sterilized gauze, absorbent cotton, broad straps of adhesive plaster, and a many-tailed bandage. At the end of a week the sutures are removed and replaced by narrow strips of rubber adhesive plaster and a similar dressing is applied as the first time, except the guttapercha tissue. The patient is kept in bed for three weeks in all. This rest I believe to be of importance to secure a solid union, and I deprecate modern advices to let the patient walk about after a few days. I am also in favor of the use for three months of a snugly-fitting abdominal supporter. To do without it while the cicatrix is still weak, invites hernia; to keep it too long weakens the abdominal muscles.

I can so much more freely recommend the method described, as I do not claim any part of it as my own invention. Paul Segond, Péan's genial pupil, has adopted it and calls it the "American method." As American gynecologists it behooves us to give due credit to Henry O. Marcy for the use of the buried continuous animal suture (1881), to T. A. Emmet for the retroperitoneal treatment of the stump (1884), to Lewis A. Stimson for the substitution of the direct ligation of arteries for the unsafe mass-ligature (1889), to William R. Pryor for having shown the advantage of coming from below upward on the second side (1894), and to Howard A. Kelly for having combined most of these ideas in a clear, precise form (1896). Thus America can claim not only to be the birthplace of abdominal hysterectomy, but gradually to have developed it to its most perfect form, the chief representative of the present period of operative gynecology, and a worthy companion-piece to ovariotomy.

CLINICAL MEMORANDUM.

A CASE OF CONFINEMENT FOLLOWING A SUPPOSED DOUBLE OVARIOTOMY AND COMPLICATED BY AN INTESTINAL HERNIA THROUGH THE OLD LAPAROTOMY WOUND.[1]

BY C. HENRI LEONARD, A.M., M.D.,
OF DETROIT, MICH.;
PROFESSOR OF THE MEDICAL AND SURGICAL DISEASES OF WOMEN AND CLINICAL GYNECOLOGY IN THE DETROIT COLLEGE OF MEDICINE.

A CONFINEMENT following a supposed double ovariotomy or complicated with umbilical hernia is not so rare an occurrence as to demand any special mention now; but, taking into account the double complications as presented in this patient, then such a case becomes of more than passing interest. The nearest similar case to this of mine, so far as I can ascertain and I have searched all the records at my command and also have written various authorities for their personal experiences, was one detailed in Dr. Kelly's work and is given further on.

My patient was very anxious as to the final outcome when she learned of her pregnancy, and I became almost equally anxious as to her prospects, and so I wrote to Dr. Humiston of Cleveland, Ohio, after consulting my Detroit colleagues as to their experience and what I might reasonable expect in my case. He replied as follows:

CLEVELAND, OHIO, June 21, 1899.

DEAR DOCTOR:—I received your letter of June 18th in due time, and in reply beg to say that personally I have had no experience in abdominal hernia following laparotomy when pregnancy had occurred, but I have attended a number of those cases who had an umbilical hernia, not the result of operation, and while they afforded some trouble, there was really no complications during the labor. It would be well to have it supported by a binder and band, or an abdominal belt that you can get from any instrument-maker, and I should not feel particularly concerned at the time of labor.

Sincerely yours,
M. M. HUMISTON.

I also wrote to Dr. Joseph Price, of Philadelphia, for his experience and his advice and the following is his reply:

[1] Read by title before the Section on Obstetrics of the American Medical Association, Atlantic City, June 5, 1900.

241 North 18th Street,
Philadelphia, July 5, 1899.

My Dear Doctor:—Your patient will suffer more than usual throughout gestation, and the hernia ring may increase very considerably in size. Pain and tenderness about the opening is due, in all probability to some adhesions—omental and intestinal—she should wear a broad, comfortable support. Take advantage of her convalescence for closure of the opening. Free bowel and omental adhesions, split sheath of both recti and close. Keep her in bed for five weeks for a strong organization.

Yours faithfully,
Joseph Price.

I then wrote to Dr. Howard Kelly, of Baltimore, and below I give his reply. His case is the only one I can find in literature which approaches mine in its singular conditions.

1418 Eutaw Place,
Baltimore, Md., July 6, 1899.

Dear Doctor Leonard:—It gives me pleasure to answer your letter. There need be no added danger owing to the hernia. I would have the patient wear a snug bandage during pregnancy, and fit her with a good tight bandage when labor comes on, to keep the uterus from hanging in an oblique position. If you will look at page 467 of the second volume of my book you will see the figure of a similar case.

Sincerely yours,
Howard A. Kelly.

Referring to the page and work mentioned by Dr. Kelly I find this brief description of his case: "Hernia of the pregnant uterus in a negress. The uterus has escaped through a ventral hernia, due to a celiotomy May 3, 1894, of which the scar is plainly seen. The patient went to term and was delivered of a living child by a normal labor."

This case varies somewhat from mine in that the uterus came through the ventral opening; whereas, in my case, the uterus was all the time held back, and only the intestines were prolapsed through it, although the macroscopical appearance of my case was very similar to that shown in the illustration.

The only other case similar to Dr. Kelly's, so far as my knowledge goes, is the one recently reported by Dr. W. V. Anderson of Toledo, O. This case was reported to the Mississippi Valley Medical Association at its recent meeting. In this case there had been no laparotomy performed previous to the hernia of the uterus. Dr. Anderson entitles his case "Complete Hernia of the Uterus," and I condense it to the following: "A large, well-developed Polish woman, the mother of ten children, had been in labor for thirty-six hours. On examination it was found that the abdominal muscles had been separated to such an extent that the uterus had passed out between the recti carrying the aponeurosis in front of it, and the whole hung like a great pear, suspended by its cervical attachments, the fundus reaching nearly to the knees. The uterus was freely movable and the os was found to be fully dilated. The uterine contractions were good, considering the length of time the woman had been in labor, but the position of the uterus rendered them ineffective, for at each contraction of the uterus, the patient would make vigorous effort to help herself, and although the uterus would rise until its long diameter stood at a right angle to the body, the contraction and shortening of the abdominal muscles instead of assisting delivery, acted somewhat like a draw-string at the mouth of a pouch, so that the greater the voluntary effort the more it interfered with expulsion. Placing the patient under chloroform, the uterus was inverted and then steadied by an assistant while the forceps were applied (the head presenting L. O. A.), and she was delivered without difficulty of a girl weighing seven or eight pounds. The birth-canal was ample, and there was absolutely no cause for dystocia but the herniated uterus and consequent effect of the contractions of the abdominal muscles."

Now, as to the conditions met by me in my case: Mrs. D., of Irish parentage, aged twenty-six years, and married four years, was about four-months pregnant when she consulted me last July. She reported having been operated on nearly seven years previously and, as she supposed, both ovaries were removed. Some two years after her marriage she became aware that both of the ovaries had not been removed. She never menstruated regularly, the menses sometimes appearing once a year, sometimes twice a year, the flow being slight and accompanied with but little pain. This was the "normal condition" down to the time of the operation. After the operation, to her surprise, and to that of her mother, she became quite regular, the first menstruation occurring the first month following the operation and this regularity continuing down to the time of her pregnancy, four months ago (as she placed it), as it had been four months since she had menstruated and she had had "morning sickness" for the past two months. This led her and her family physician to think that she must be pregnant. She was in a fair condition of health, and, excepting the fear of serious complications, like the tearing through of the abdominal walls by the enlarging uterus at the time of labor, she was well satisfied with her new condition.

After quite careful examination, I confirmed the previous diagnosis of pregnancy; but, as to the prognosis, I was somewhat at sea, as I never saw or read of such a case; hence, the reason for the letters of inquiry addressed to Drs. Hunniston, Price and Kelly, as above given. The hernia that was then presenting was, when she was on her feet, of the size of two fists, irregular in shape; this irregularity, in part, being due to different thicknesses of the integumentary coverings. Where the skin was the thinnest, there the swelling would be much the larger; at one place this covering was so attenuated that it seemed as

thin as parchment, and here was a grape-like protrusion of bluish tint; that was a little to the left of the median line. On lying down all this could be quickly manipulated back into the abdomen. The hernial opening was in the middle of the scar of the incision made some seven years before; it was about 1¼ inches in length, and you could not quite insert two fingers into the abdominal cavity through it; the marginal edges were quite thick and firm, except at the top and bottom; here they were very attenuated, and seemed as if they would easily tear to the full length of the original incision; the upper end is two inches below the umbilicus, and the lower end about that distance from the pubes; the scar is nearly ¾ of an inch in width, so much has it been stretched, and about four inches in length. The hernial opening is about in the middle of the longitudinal length of the scar, the middle of the opening being about 3½ inches below the umbilicus.

This being the condition of affairs, one had quite a different problem for solution than if it was pregnancy complicated with an umbilical hernia; for here, in my case, the uterus was bound as it enlarged, to present its fundus at the old laparotomy opening, and as the throes of labor approached and the contractions of the abdominal muscles to aid in expulsion came on, there was great danger of tearing the whole wall open; the parchment-like thinness of the upper and lower edges, and of parts of the cutaneous covering being the same, there was danger, unless one was guarding well the walls during labor, that one would get a complete rupture through the external abdominal surface as well.

She had been wearing an abdominal belt with a concave pad, and had succeeded, up to the time of her pregnancy, in keeping the hernia well in hand. But, with the pressure of the enlarging uterus to contend with, I advised a *convex* surface to the pad, and a more tightly applied band, as the hernia was enlarging all the time, this due to the uterine pressure from below.

In spite of these very peculiar and in some ways foreboding conditions, I took the cheerful side of the prognosis, and assured her that although I had never seen or read of a similar case, I believed her conditions were much more favorable than to have a forced abortion, as she had thought might be necessary; that I thought the dangers from the abortion would far outweigh those from labor at term, even with these peculiar conditions. To get further light for myself, and to reassure her as far as possible, I addressed the letters to my confrères, as above indicated, and I can assure you that all of us were heartily glad to get their messages of good cheer.

From this time onward she went on to nearly full term with cheerfulness and with a minimum amount of serious complications. The convex pad of about three inches in diameter and the quite wide and tight band of knitted silk and rubber seemed to hold both the intestinal hernia back and also control the presenting uterus, so that full term was reached with the patient in as good condition as falls to the lot of the majority of women. Our words of good cheer kept her buoyed up, and her desire for a living child led her to make willingly the sacrifices of exercise, etc., and during the growing times of the intra-uterine life of the child, she regarded this curtailment of personal pleasures as a pleasant sacrifice for her.

Having long since given up the practice of obstetrics, and also expecting that I might be absent from the city at the expected time of confinement, I asked Dr. A. H. Steinbrecher, of the Detroit College of Medicine, to look after the accouchment of the patient; he saw her at intervals leading up to the time of labor, and finally was hastily summoned a little before the time expected, to look after the final act of pregnancy. To his surprise, and to the surprise of all, the labor progressed rapidly through its various stages to completion, with little or no trouble from the hernia, or of danger of the uterus being forced out of the unadherent edges of the intra-abdominal wound. He had no difficulty in keeping control of the uterus by pressure over the old laparotomy opening; the weakened abdominal muscles delayed but little, if any, the various stages of labor or recovery. There was no trouble with the afterbirth, nor was there increased hemorrhage. The woman was delivered of a fine boy and she made an uneventful recovery from the confinement.

The subcutaneous opening is still there into the abdominal cavity, and the hernia still descends into it when the abdominal supporter is not used; but, otherwise, she seems not to suffer from her somewhat peculiar yet interesting (from an obstetric standpoint) deformity.

MEDICAL PROGRESS.

Spondylitis after Typhoid Fever.—A. Schantz, referring to this rare sequela of enteric fever (*Archiv f. Klin. Chir., Bd. 61 Heft 1, p. 605*) says that the first two cases were reported by Quincke and the third instance of the disease was recently published by Könitzer during the past year. The last case on record is that of the author with the following epitomized history: Female, aged thirty-six; married; no vocation other than housewife; taken ill early in April, 1899; admitted to the Leipsig Hospital on the 14th; severe typhoid fever; distinct rose spots; marked Widal reaction; early in the course appeared right-sided otitis media suppurativa and superficial ulcers on the sacrum; April 18th suppuration attacked and finally totally destroyed the right eye; May 26th patient was seen to be very weak in the legs, complaining of much pain on attempting to walk. June 1st discharged. Three weeks after admission she was suddenly attacked by violent lightning pains in the right leg with twitchings, also pain and total disability of the right shoulder. Two weeks after this pain of the same character appeared in the sacral region. Swellings were

palpable over the areas of pain. After discharge the patient suffered more and more from the pains and was confined to her bed. Although rest in bed made the pains less severe, they made sleep impossible. Her general condition deteriorated rapidly. During this interval several examinations, medical and gynecological, were made, without any diagnosis. The author saw her first on July 15th, while assisting at enucleation of the eye and made the diagnosis of spondylitis. There was tenderness on pressure over the lower lumbar vertebral spines, which on percussion awakened deep, dull pelvic pain. Muscular rigidity and fixation of the vertebral column were also distinct. No deformities. No swellings. Active patellar reflexes. No ankle-clonus. Light twitchings of the adductors. The right shoulder was in strong contraction. August 22d the patient was finally brought under treatment. During this interval she had become unable to walk. The usual orthopedic apparatus and jacket were applied with remarkable and prompt results. After six weeks she was able to sit up one hour daily, which intervals were slowly increased and attempts at standing and walking made. November 13th discharged with no pains, some weakness of the knees, normal reflexes. January, 1900, she was in excellent health, going about the house, taking walks an hour long, although still using the apparatus and exercising great care. The diagnosis here lay between an infection other than typhoidal of which the eye and ear disease may also have been expressions and a typhoid secondary invasion. The distinct and typical symptoms and course of the attack make it beyond doubt to have been a case of typhoid fever, followed by the foci of secondary suppuration. The first case of Quincke may not have been an example of real involvement of the bony so much as of the muscular structures, because it presented features which are not usual in frank cases of spondylitis. These facts were a tenderness over the lower lumbar and upper sacral spines which after four days shifted to the tissue adjoining them and after twelve days more was acute over the tenth and twelfth dorsal spines. Such variations of the site of pain and tenderness do not appear in true disease of the vertebræ. In the other three cases no such conflict between the histories of a Pott's disease of the spine and those quoted exists. It is possible that an existing, slowly progressive, entirely latent tubercular disease was excited to violent activity by the typhoid fever. But in the absence of any previous history pointing toward that condition and in the presence of the direct connection between the primary and secondary manifestations makes it very probable that the bacillus typhosus was responsible for the whole. The pathology of typhoid bone-disease and its symptoms elsewhere in the body are so well known that a review of the ordinary course one might expect of such a spondylitis will be instructive. Its occurrence will be in comparison with other typhoid osseous lesions as frequent as the parallel in tuberculous bone-disease, and its onset should occur at about the same time as the other foci of the bacillus typhosus secondary to the original invasion, namely, there will be very early, very late appearances and others just at the beginning of recovery. The very tardy cases will be difficult to differentiate from tuberculous lesion. The degree of the sickness will also vary between acute, subacute, chronic, temporary and prolonged attacks. The presence and absence of deformity will be according to age, rare in adults; and to destruction of the bone, absent when none has occurred. Abscesses also must occur in the long attacks whose contents alone will pronounce their identity as typhoidal. In general the sudden intense invasion soon after or in connection with the enteric state will suggest the origin, as will the presence of suppurating foci elsewhere in the body. Over 40 per cent. of all typhoid bone-disease show multiple scattered lesions, as in the author's case, shoulder, eye, and vertebræ. Finally with reservations Widal's reaction will aid. The treatment suggested is rest, maintained in the mild cases by simply keeping the patient in bed, in the severe and intense cases by applying suitable apparatus or jackets.

Erythromelalgia.—A short and comprehensive review of what is known concerning erythromelalgia is given by M. Kahane (*Klin. therap. Woch.*, May 20, 1900). In the earliest cases observed, the toes were affected and the disease then showed a tendency to spread upward, but since then the upper extremity or both upper and lower extremities have been seen involved and even internal organs, such as the brain, testicles, etc., have been the seat of the peculiar process. The pains, which are so prominent a feature, are of burning or stinging character and often extreme in degree. They may be paroxysmal, but later become continuous and may be intensified during the night and with hot weather. The discoloration may be of a bright red or more of a bluish hue and is diffuse or circumscribed, sometimes with nodulations. Hyperesthesiæ and paresthesiæ of touch and pain often occur. Of other nerve-disturbances there may be mentioned paresis of the limb, hyperidrosis and, in old cases, trophic changes such as sclerosis, atrophy, edema, rhagades, ulcerations and depraved nutrition of the nails. It is impossible as yet to explain the nature of the disease, since it is not even settled whether it is to be looked upon as an entity by itself or merely as a manifestation of certain disorders of the nervous system. The pathology, also, demands further study, but it is clear that in some cases neuritis and perineuritis, as well as diseased vessel-walls, are present in the affected parts, while the cord may show the lesions of tabes, myelitis, syringomyelia, etc. Several cases which seemed to depend on functional nervous disorders, especially hysteria, have been described, yet it is possible to have nothing but the local changes. The usual causes of neuritis,

such as exposure, overexertion, malaria, syphilis, etc., must also be regarded as bringing on erythromelalgia. There is no uniform method of treating; some do best with rest, elevation and the application of ice, while with others hydrotherapy, electricity and massage with ichthyol or ethyl chloride locally and the salicylates, antipyrine, ergotine or morphine internally may achieve a cure. When dependent on some underlying disease, this must be treated. The course is apt to be chronic.

Alcohol and the Death-rate.—Although the use of alcohol is an important factor in regard to the prognosis of disease, it seldom figures as the cause of death. Yet it is the direct cause of death, says Ch. Fernet (*Bull. de l'Acad. de Méd.*, May 14, 1900) in the accidents of drunkenness, such as injuries, exposure to cold, etc., or when excessive drinking results in a fatal acute gastritis, or gastro-enteritis, hepatitis, or pneumonia. It is a direct or more remote cause when it produces the ultimately fatal chronic conditions of arteriosclerosis, cirrhosis of the liver, interstitial nephritis, inflammation of the stomach and intestines, cardiopathies and meningo-encephalitis. By inducing delirium tremens or from having lessened the recuperative power of the body, it is an indirect cause of death through rendering more fatal such acute infections as pneumonia, influenza, erysipelas, etc., and certain traumatic lesions. More indirectly still does it cause death by reducing the resisting power, and rendering the body more susceptible to infection, or by causing abortion or the procreation of non-viable or mal-developed infants.

The Surgery of Liver Abscesses.—J. Smits (*Arch. f. klin. Chirurgie*, B. 21, Hft. 1, p. 173) mentions 21 cases of hepatic suppuration, of which 3 resulted fatally, although all were treated by operation. These cases all occurred in the tropics. The author describes the various surgical methods of dealing with the condition, puncture with aspiration or drainage, and the open operation with wide exposure, free immediate evacuation, and continuous efficacious draining of the abscess cavity. Puncture is valuable chiefly as a diagnostic procedure and it carries three dangers, namely, sepsis, damage to one of the main blood-channels resulting in fatal hemorrhage and entrance into a neighboring organ which may be intolerant of traumatism. As a rule, the exploratory use of the needle should be made part of the treatment and the operation should follow at the same sitting. After the needle has been driven through skin and muscle, it is stated as good practice to draw out and secure the piston so that a vacuum is made for a part of the capacity of the cylinder. The needle is then pushed in until this safety vacuum is filled with pus. In this way danger of passing the instrument through and beyond the abscess into sound liver-tissue is avoided. By making the aspiration part of the treatment the needle may be carried across the pleural and peritoneal cavities with scarcely any danger of infecting them. The author states that, although frequent deep punctures with large needles have been his rule, in none of his cases did he get a single bad result therefrom. After pus has been located he withdraws the needle until the pus no longer flows into the cylinder and then consigns the aspirator to an assistant who holds the needle *in situ* as a plug to its track against outward flow of the abscess-contents and as a guide for the evacuating incision. The mere puncture of an abscess and aspiration as curative measures are condemned on the grounds that they give no means of establishing complete evacuation or of providing against rapid recurrence of the pus. Eleven cases, with ten deaths and one recovery only after spontaneous rupture of the focus into the lungs, are cited as proof of his argument. The use of the trocar and cannula, followed by the insertion of a drain-tube through the latter before its removal, is also trustworthy. Its sphere is only as a temporary relief of superficial abscesses about to point through the skin, so that the patient may be more comfortably and safely transported to the hospital. The first radical operation is the simple wide incision obviously available only in foci at the stage of spontaneous emptying through the skin. As a curative measure it is usually insufficient but may be used like the trocar as a temporary palliative. Another crude and occasionally successful method is to open the liver along the aspirating-needle through the abdominal cavity, when adhesions may or may not have occurred, while the assistants force the liver against the parieties. The pus is then rapidly evacuated. Its successes certainly must have been due to abundant previous adhesions, but clinically the presence of these is often very difficult to establish in advance. None of the foregoing curative attempts fulfil the final indication of all abdominal and pleural operations, namely, the walling-off of the main cavities both during the surgical manipulations and during the after-treatment. The older methods of accomplishing these points consisted in the primary exposure of the organ, packing the wound with or without the suture of parietal and visceral serosæ, and, after sufficient delay for the establishment of the protecting adhesions, the secondary treatment of the abscess. Entire clinical success followed the use of this method in 16 out of 19 of the author's cases. The fatalities had no relation to the operative technic. The primary methods *per se* depend upon the immediate necessity for opening the abscess and are subject to two variations in detail, first, suture of the serous layers together before opening the suppurative site; second, tamponade of the adjoining approaches to the general cavity, then evacuation of the pus followed by suture of the peritoneal leaves directly or after creating flaps of the membrane to compensate for recission of the liver. The author's choice rests with the latter technic. In addition to the thoracic approach through pleural adhesions or through the parieties just distal to the

pleural margin, there remains the method of inevitable opening of the pleural cavity. Here, again, we have the primary building of adhesions and the subsequent evacuation, or the immediate suture and tamponnade of the pleural divisions and primary attack upon the suppurating liver. The pleural leaves may be sutured alone, together, or strengthened by flaps of diaphragm tissue. With care both methods result favorably. The last operation used by the author in one case with entirely good outcome was that of resection of the lower anterior thorax-wall after Lannelongue, adapted to abscesses beneath the costal cartilages. Here the cartilages of the eighth, ninth, tenth and eleventh ribs are exposed and resected, the parietal and visceral peritoneum managed in one of the foregoing manners, and the disease treated. The resulting damage to the thoracic and abdominal walls appears rather immaterial as the muscle-functions can by care be largely spared. The after-treatment is concerned with keeping the outer dressings clean, the drain-tubes patent and drainage active, and with the entire absence of irrigation, curettage stimulation or other interference with the abscess-cavity. Any such treatment may cause an extension of the disease or an obstinate flow of bile which would otherwise have been stopped by the processes of nature already present. The prognosis depends upon the early diagnosis and prompt thorough management of the disease. Great emphasis is laid on the fact that of the author's patients 11 had had intense single or repeated malarial attacks, while only 4 gave a history of dysentery and 1 of diarrhea. His treatment was distributed as to methods and results as follows: Primary and secondary operations, transpleural 12, cures 11; abdominal 6, cures 4; Lannelongue's operation 1, cure 1; primary and immediate evacuation, transpleural 1, abdominal 1, each cured.

Seasickness.—At this season of the year the suggestions in regard to the treatment of seasickness made by H. Partsch in the *Med. Rec.* (June 9, 1900) are most apropos. A long experience on ship-board has taught him that previous preparation is unnecessary and useless. Rooms amidships are preferable and good ventilation is extremely important. For the first few days, lie down most of the time, keeping the eyes closed and avoid excitement or tiring conversation. Whenever the slightest sensation of illness is felt lie down at once and close the eyes. Usually only one pillow should be used and if very ill no pillow at all. Seasickness is the result of the disturbance of the circulatory apparatus and the accumulation of blood in the relaxed abdominal blood-vessels. Retching is Nature's method of flooding the brain, and vomiting and nausea are merely incidental, not essential. An abundance of nutritive material is necessary. One should eat about seven times daily, and the sicker the patient the oftener he must eat and the less at a time. When seasick the easily-digested fluids are best, such as ale, porter, stout, broths, soups and meat extracts, the desires of the patient being considered. Food should always be taken at least ten minutes before arising in the morning, and when the patient is ill food should be taken without raising the head. The worst case of retching will be easily made comfortable in at least thirty minutes, by lying down without a pillow, closing the eyes and taking a pint of stout in six doses at five-minute intervals. Another food is made by mixing the yolks of two raw eggs with an equal amount of brandy and giving a teaspoonful at ten-minute intervals. The best time to take any beverage or food is just after a paroxysm of retching. Should it be taken before and thrown up, then take another dose immediately afterward and that will stay down. Severe headaches may be controlled by bromide of sodium in thirty-grain doses, to be repeated in one hour.

Recurrent Diphtheria.—In the *Med. Chronicle* (May, 1900) R. W. Marsden has reported three cases of laryngeal diphtheria treated by the antitoxin method which after entirely recovering from the original attacks had reinfections after twenty to twenty-five days necessitating in two cases a second tracheotomy. Another case of tonsillar diphtheria had a recurrence five weeks after the first infection. The question raised is whether these were cases of self-infection or due to a reinfection from without, and how long immunity from the disease lasts as a result of antitoxin injections. The author does not believe that exposure to the germs outside is necessary for the explanation of these recurrent attacks and when an attack has been terminated by the use of antitoxin, immunity from the disease may end at the expiration of three weeks. It is interesting to note that in each instance the second attack was of an exactly similar type to the original one, seeming to prove that the primary set of infection predisposes that part for some time to a reinfection. The author believes that during convalescence from an attack of diphtheria, the reinjection of antitoxin must be immediately performed upon the supervention of "croupiness" or signs of laryngeal stridor.

Bromide Treatment of Opium Habit.—Dr. Macleod of Shanghai reported in 1897 a series of several cases of the opium habit which he had treated by a method known as the "bromide sleep." He has since had three cases and of his series two deaths have occurred, one presumably of pneumonia and the other of a septic intoxication. In the *N. Y. Med. Jour.* (June 9, 1900) A. Church gives a detailed account of two such patients treated by the bromide method, one, a physician under his own care, gave very alarming symptoms of cardiac and respiratory disturbances during the treatment and seemed unlikely to recover. A slow but most satisfactory convalescence followed without any further desire for morphine and with a marked improvement in the general condition. The other case developed an exacerbation of a chronic nephritis

and died of uremia on the twelfth day. Enormous doses of sodium bromide were used by mistake in this latter case and probably induced the nephritis. Macleod's results were very satisfactory and obtained with greater certainty and more rapidly than by any of the ordinary methods. One hundred and twenty grains of sodium bromide are given every two hours in a half-glass of water until one ounce is given on the first day. On the second day a smaller amount is given and this may be sufficient or the doses may be continued on the third day. If the patient cannot be roused the administration may be ceased after twenty-four hours. The drug acts in a cumulative way and the sleep tends to deepen oftentimes for forty-eight hours after the drug is stopped. It is claimed that the intense suffering, vomiting, sneezing and cravings for morphine, which usually mark its sudden withdrawal, can be avoided by this method. The tendency to relapse seems to be reduced to a minimum, but the method is not without its dangers.

Rheumatoid Arthritis, Gout and Rheumatism.—The diagnosis of chronic rheumatism is, no doubt, very frequently made for other conditions, such as rheumatoid arthritis and gout, and yet it is very important that the mistake should not be made. An excellent article appears in the *Practitioner* (May, 1900) by A. P. Luff on the distinguishing features of these affections. Rheumatism in the chronic form usually affects the joints, but may not manifest itself as an arthritis at all, but by producing a chorea or erythema nodosum or by affecting the muscles alone. Salicylate of soda is a rough method of diagnosis for nearly every case of true rheumatism will respond to it. Chronic rheumatism never produces a marked deformity, such as lipping of the cartilages and bony outgrowths. The pain is usually more acute and flies from one point to another. The distinction between gout and rheumatoid arthritis is more difficult. Gout appears most commonly in males, among the well-to-do. It is improved by a restricted diet. The onset is sudden and obvious and usually begins in the feet with swelling and inflammation. Rheumatoid arthritis most commonly occurs in females and among the poor and ill-nourished, and is improved by full diet. The onset is insidious and there is at first no observable swelling of the joints. Although it ultimately affects many joints, it frequently begins in one of the joints of the thumb and gradually spreads to other joints especially of the hands. The temporomaxillary joint is never affected in gout but frequently in rheumatoid arthritis. Another important distinction is that a remarkable symmetry occurs in the affection of the smaller joints of the hands in arthritis but never in gout. This symmetrical nature of the disease has caused a nervous origin to be suggested, but the author does not believe this to be true, because the disease does not begin symmetrically. Furthermore the muscular atrophy is probably wholly of disuse, no reaction of degeneration is ever found and no anatomical lesion of the nervous system has been seen post-mortem. It is now believed to be an infectious disease and recently diplococci have been cultivated from the joints of an undoubted case of rheumatoid arthritis, which when injected into rabbits caused a similar articular disease to that from which the patient had suffered.

Tuberculosis in Colorado.—In Denver in 1893 the number of deaths from tuberculosis was 435; in 1898 the number was 501. In 1893 the number of deaths from tuberculosis specified as contracted in Colorado was 49, or 11.26 per cent. of all deaths from the disease; in 1898 the number was 99, or 19.77 per cent. This increase in the number of deaths from tuberculosis contracted within Colorado resulted in the appointment by the State Board of Health of a committee to investigate and outline a plan whereby the unnecessary spread of the disease might be restricted. G. E. Taylor (*Jour. Am. Med. Assoc.*, June 2, 1900), one of this committee, tells of the scope and results of the inquiry and of the measures agreed upon to lessen the spread of the disease. The scope of the inquiry included all possible sources of infection. These may be divided into three classes: (1) The expectoration of consumptives. (2) The milk from tuberculous cows. (3) The flesh of tuberculous animals. It is known that the expectoration of consumptives contains the tubercle bacilli and that these bacilli are the cause of tuberculosis in others. While the expectoration remains moist the bacilli are not distributed in the air, but as soon as it dries they are freed and float in the air, and are inhaled and cause the disease in others. Inasmuch as the danger increases as the sunlight and fresh air decrease, there is greater danger from indoor expectoration than from outdoor spitting. It has been proved, however, that there is danger of infection from the expectoration of consumptives even after thirty-five hours of exposure to direct sunlight. There is danger of infection from the expectoration of consumptives in all stages of the disease, even in the very early stages. Those liable to be infected from this source are: (1) The consumptive himself, who undoubtedly often reinfects himself by carelessness and so brings about a fatal termination of his disease which might have been conquered. (2) All persons who associate more or less intimately with the consumptive. (3) The public generally by the expectoration on the streets and in other public places. (4) Animals are liable to contract the disease from the expectoration of human consumptives. Cows suffering with tuberculosis may give milk containing tubercle bacilli. This may obtain without the cows presenting sufficient symptoms to arouse even a suspicion that they have tuberculosis. There is no doubt that milk from tuberculous cows is a great source of danger, and that attention should be paid to it. A large amount of investigation and

numerous experiments have demonstrated that the flesh of tuberculous animals may transmit the disease to those eating such flesh. Thorough cooking kills the bacilli, but so much meat is eaten rare that it should be subjected to thorough inspection. The writer cites that in New York City, for six years, the annual death-rate from tuberculosis per 100,000 among the Russian Polish Jews was but 70.72, while for the remainder of the population it was 427.75, and he wonders if their scrupulous care as to meat inspection has not something to do with their wonderful relative freedom from the disease. There are practically only two ways of determining the presence of tuberculosis among cattle, *viz.*, post-mortem inspection and the tuberculin test. The latter method, which the writer describes, is the only satisfactory one. When tuberculosis is discovered in a herd (1) the reacting animals should be branded and separated absolutely from the non-reacting animals; (2) the barn which they have occupied should be thoroughly disinfected; (3) no milk from the reacting herd should be sold; (4) it is not necessary to slaughter every reacting animal, for, unless the tuberculosis is general, the animal may be fattened for beef, provided a thorough post-mortem inspection is allowed. The following measures to lessen the spread of tuberculosis among animals and mankind in Colorado were agreed upon by the local and the State Boards of Health and are to be carried out by their officers: (1) The education of the public by a circular setting forth the dangers from expectoration and from the milk and meat supply, and the measures necessary to prevent the danger. (2) Public expectoration should be lessened by proper placards and be prohibited by ordinances in the larger places of the State. (3) All rooms where deaths from consumption are reported should be disinfected immediately by local health officers. (4) All insane asylums, prisons, reformatories, and hospitals should be required to keep tubercular and non-tubercular inmates separate. (5) Dairymen should be compelled to produce official certificates of freedom of their herds from tuberculosis before they are given permits to sell milk. (6) The employment of tubercular persons on dairy-farms or at milk depots should be absolutely prohibited by ordinance. (7) Ordinances should be passed prohibiting private slaughter-houses and requiring that all animals be slaughtered at public abattoirs under competent inspection. (8) The active aid of the public press should be enlisted in furthering all phases of this important work.

Operative Treatment of Simple Fractures.—W. A. Lane (*Lancet*, May 26, 1900) says the supposition that the surgeon can "set" fractures satisfactorily and retain them by splints is purely mythical especially those of the leg; also the idea that muscular spasm is the factor opposing accurate apposition of the fragments is equally fallacious. The muscles form ties between the end of the bones, and after a fracture these ties have their transverse axes increased by hemorrhagic and inflammatory exudate, and, therefore, their long axes must be shortened thereby, causing and maintaining deformity. This view is proven by the fact that under anesthesia with complete muscular relaxation, it often requires great force to replace the fragments in proper position. Failure to secure perfect apposition often leads to persistent pain, interference with the functions of neighboring muscles, and often causes changes in neighboring joints. In cases of simple fracture, especially in the bones of the leg, where accurate apposition (determined by radiograph) cannot be obtained, incision should be made and the fragments properly fixed by suture, peg, screw or other mechanical means.

Epicarin.—This new therapeutic agent is a combination product of kresolin and beta-naphtol, easily soluble in alcohol or ether. It is a powder of slightly yellowish color and has been proven free of any poisonous or inflammatory reaction. The action of epicarin externally applied is to produce mortification of the superficial layers of the epidermis and occasionally to produce a slight exudation. The scope of its administration is coextensive with that heretofore accorded to naphtol, namely, scabies and the dermatosycoses. In scabies the best method of application is a ten-per-cent. ointment. The annoying itching ceases very often after but one application of the ointment. In prurigo the most surprising results have been attained with epicarin. In this affection the entire body of young children was rubbed with the ointment as often as ten times without causing either albuminuria or other disturbances. In herpes tonsurans a ten-per-cent. alcoholic solution may be used as well as the ointment with good results. For scabies, eczema squamosum, etc., the following formulæ are suggested:

1. ℞ Epicarin 10.0
   Unguent. simpl. 100.0
   Ft. unguent. Ext. use.
2. ℞ Epicarin 10.0
   Spir. Vin. gallic. 100.0
   Spir. Vin. lavand. 25.0
   Glycerin 10.0
   M. Sig. As a wash.—*A. Kaposi* (*Wiener med. Wochenschrift*).

Inflammations in Serous Membranes.—In discussing the pathology of adhesions as they occur in the pleura and peritoneum, G. Muscatello (*Münch. med. Woch.*, May 15, 1900) states that the pure and simple desquamation of the surface endothelium is not sufficient to cause an agglutination between adjacent surfaces, but that this process must always be preceded by a true inflammation with exudation of fibrinoplastic material. Furthermore, the author emphasizes that when all the conditions necessary to produce cohesion between two surfaces are present, the fact that the endothelium has not been lost will in no wise interfere with the process, as has been recently stated.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscripts should be typewritten.

INFECTIONS AND DECREASE OF VIRULENCE.

No statement is heard more frequently at medical society meetings than that the ordinary infectious diseases are much less virulent than they used to be. A corresponding statement as to the mildness of our present-day writers is constantly heard from the "oldest inhabitants." As a matter of fact, consultation of the statistics of the weather bureau during the last sixty years, shows that the average temperature of our climate has not changed perceptibly within the memory of any one now living nor as long as statistics have been kept.

There is a tendency in human nature to remember early impressions very vividly and to exaggerate their importance in comparison with observations made later in life. Man remains as truly to-day as in Horace's time *laudator temporis acti se puero*, apt to think the past more significant than the present. The fact is, the more serious epidemics, just as the severer winters, produce a vivid impression that is regarded later on as the average, instead of the extreme, experience.

Improvement in hygienic conditions has undoubtedly limited the spread of contagious diseases and very probably modified their fatality. The change is not, however, as great as has been claimed by some of the older practitioners. The old contagious diseases, like bubonic plague, the history of which can be traced for millenniums, have remained absolutely unchanged in their essential characters and in the fatality they cause under favoring conditions. This persistence of the natural characteristics of certain diseases during centuries has been quoted by biologists as a convincing demonstration that species do not change under the influence of time and environment. Thousands of millions of generations of the bacillus of bubonic plague have come and gone since the disease firs. made its appearance in history, yet men are affected in just the same way as they were, according to the first historical accounts, and the mortality from the disease is not a whit the less to-day than it was originally.

In this question of the modification of virulence of contagions we are face to face with one of the great biologic problems, the variation of species. Either specific bacilli have lost their power to harm, a quality that is inherent in their essential parasitism, or man has gained in vital resistance a fundamental property that depends on his natural metabolism. Careful scientific observations have not been extended over a sufficiently long period of time to affirm or deny either of these propositions, but the probabilities are that neither is correct.

THE PATHOLOGICAL INSTITUTE.

WE present this week a temperate, dignified letter from Dr. Van Gieson which to a certain extent sets forth his attitude, as Director of the Institute, toward the position that has been assumed by the President of the State Lunacy Commission. Accompanying it are the protests that have been signed, attesting the high estimate in which the work of the institution is held and the resentment that is aroused by the present effort to suppress its research work. An indignant protest from Dr. Spitzka follows.

The men who have signed these protests are the leading neurologists and psychologists of the world. No more convincing testimonial to the value of the research work already done by the Institute, and the promise this work gives of future achievement, could be presented than is contained in these protests against the blighting influence of the Lunacy Commission. When we recall the fact that Dr. Wise himself is on record as extolling the work of the Institute and

bidding it Godspeed, and that the greatest minds of the world in this specialty are adding their testimony to the value of the work, wonder is aroused as to the cause of the new attitude assumed by the Commissioner. The sting of conscience in reference to opinions already expressed by him has come very suddenly and the question suggests itself: Why this change of heart? The longer the Institute exists and the more research work it accomplishes, the stronger grows the faith in its power to throw new light upon the subject of psychopathology.

The law announcing the purpose of the Institute distinctly includes pathological research. As we have said over and over again, the pathology of insanity is absolutely unknown. Dr. Wise speaks of the modern treatment of the insane and points to it as one of the triumphs of clinical observation and study, but every one knows that what he calls *the treatment of the insane is only the application to insane people of the ordinary rules of hygiene, sanitation and dietetics, together with the treatment of intercurrent medical and surgical diseases.* But treatment of insanity—the condition which justifies the presence of the insane in the State Institution—there is none. State hospitals are custodians of the insane, and bear very much the same relation to the inmates as the physician of the penitentiary bears to its inmates. Both look after the hygienic and sanitary conditions and both treat any intercurrent diseases or conditions that may arise. But no more treatment is known or applied to insanity, *per se*, than is known and applied to the mental or moral degeneracy that produces crime. Until some knowledge of the pathology of insanity has been gained there is no possibility of any scientific treatment of it, and the only hope of obtaining this requisite knowledge lies in the work instituted by Dr. Van Gieson of the New York Pathological Institute and in similar institutions. The interests of the insane, the interests of the State, the interests of humanity are enlisted in unravelling the secret with which the Institute is wrestling. As we said before, Hands off! Give it time and opportunity.

ECHOES AND NEWS.

NEW YORK.

New York Hospital Appointments.—Dr. Alexander B. Johnson and Dr. Percival R. Bolton have been appointed Visiting Surgeons to the New York Hospital to fill vacancies caused by the resignations of Dr. William T. Bull and Dr. Robert F. Weir.

Dr. Pilcher Honored.—At its recent Commencement, Dickinson College conferred the degree of LL.D. upon Dr. Lewis S. Pilcher, editor of the *Annals of Surgery*.

A New Gouverneur Hospital will be built immediately on the site of the present very much dilapidated structure at Gouverneur Slip, between Front and Water Streets.

The Presbyterian Hospital has just received a donation of $200,000 to be devoted to the erection of a new pavilion.

Censure of Bellevue Officials.—An inquest was held on June 6th in the case of an insane negro who died in Bellevue of internal injuries which he received during a violent struggle with three attendants. The attendants were not blamed, but the authorities were censured "for failure to discover the extent of the injuries."

Contagious Diseases.—For the week ending June 9, 1900: Measles, 419 cases and 21 deaths; diphtheria, 294 cases and 43 deaths; laryngeal diphtheria (croup), 7 cases and 5 deaths; scarlet fever, 101 cases and 7 deaths; smallpox, 4 cases; chicken-pox, 2 cases; tuberculosis, 203 cases and 130 deaths; typhoid fever, 31 cases and 4 deaths; cerebrospinal meningitis, 8 deaths; totals, 1079 cases and 227 deaths. Death-rate for the week ending June 10 in New York City was only 15.71 in a thousand as compared with 21.44 for the same week last year and 21.77 in 1898.

Insane Asylum Fete.—The patients and employees of the Manhattan State Hospital for the Insane held a carnival of sports May 30th on the grounds of the hospital on Ward's Island. One event was a basket-ball contest among the women. The "chronics" from the Verplanck Building, who were dressed in brown, played against the "acutes" from the branch buildings, who appeared in blue. The games were refereed by Dr. Archibald Campbell.

A Feigned Cripple.—One Henry Miller, twenty-six years old, was taken to the 125th Street police station on a charge of vagrancy. One arm was done up in splints and bandages and hung in a sling. His head was bandaged above the eyes. At the station he said he had just left the Mount Sinai Hospital. When it was attempted to remove his bandages he fought lustily and gave evidence of still having great vitality. The bandages were all removed, upon which Miller was found to have sustained no injury. He admitted having carried on the deception for three weeks. He was committed to jail for six months in default of a $500 bond.

Licenses for Maternity Hospitals.—The Appellate Division of the Supreme Court has affirmed the conviction of Louisa Wagner upon the charge of having violated a provision of the Penal Code prohibiting the maintenance of a ma-

ternity hospital without securing a license. The requirement of a license, the Court said, is to enable the public authorities to make proper sanitary regulations as to such institutions, so that their inmates would not be exposed to infection or the dangers that arise from improper medical attention, and also to insure that such institutions shall not be perverted to improper uses.

His Blood for a Price.—A man who called himself Joseph A. Reynolds wrote to Superintendent O'Rourke of Bellevue Hospital on May 31st, offering to sell a portion of his blood for transfusion to any "anemiated" person who might require it. This he wished to do "to save his wife and himself from starvation." The Superintendent made public the letter, upon which a number of reporters visited the so-called Reynolds. To them he divulged "the sad, sad story of his life and his real name." Some of these reporters were in reality detectives employed by the State of Massachusetts, in which State he is "wanted" for forging bounty checks. His own statements to these reporters have brought about his imprisonment. In the meantime an emotional public had read his letter in the daily press and had contributed sufficient to make "Reynolds" comparatively wealthy.

A Woman Swindler Imprisoned.—A woman who calls herself Mrs. Bridget T. Redmond was recently convicted of swindling persons from whom she collected subscriptions for the Guardian Angel Nursery at 98 Varick Street. It is said that her real name is Catherine Fay, and that she has already been convicted of a similar offence in Philadelphia. Justice McKean told her that she had not only swindled many honest people, but had by her actions tended to cast a doubt over the honesty of many persons making similar appeal for support. She was sentenced to one year's imprisonment in the penitentiary.

Resolutions Upon the Death of Dr. Gray.—The members of the New York Neurological Society wish to record their profound sorrow at the untimely death of Dr. Landon Carter Gray. As one of the earliest members of the Society, he was ever zealous in its behalf, and during many years of his activity added much to the interests of its meetings. His work was characterized by care and thoroughness in preparation; his thoughts were soberly presented in the light of a large clinical experience, and his conclusions were those of a sound thinker. In every line he wrote and in every word he spoke there was evidence of broad culture and refinement. He was a kind friend to many, disposed to help those who sought his counsel, and was always ready to allow for honest differences of opinion.

WHEREAS, the members of this society have sustained a severe loss in the death of their honored friend and colleague,

Be It Resolved, that this acknowledgment of Dr. Gray's estimable qualities be recorded in the minutes of the Society, and that a copy of these resolutions be sent to the *New York Medical Record*, the *New York Medical Journal*, and the MEDICAL NEWS.

B. Sachs, M.D., Chairman.
Charles L. Dana, M.D.
Frederick Peterson, M.D.

Death of Dr. Paul Gibier.—Dr. Paul Gibier was thrown from a buggy in a runaway accident and sustained a fracture of the skull on June 10th. He died a few hours afterward. The disaster occurred near the medical institute of which he was the head, at Suffern, New York. Dr. Gibier was born in France in 1851. He was a graduate of the Medical University of Paris. For his investigations of the cholera in Spain he received a gold medal and for his work upon the same disease in the South of France he was made a Chevalier of the Legion of Honor. His Government sent him to Florida and Havana in 1888 to study yellow fever and on his way home he stopped in New York City, whence he returned two years later and established the Pasteur Institute for the inoculation of persons bitten by rabid animals. The establishment at Suffern is a county branch. Dr. Gibier's successor in his work will be his nephew, Dr. G. G. Rambaud, who has long been associated with him.

Dr. Gibier was a man of magnificent physique. He never used tobacco or stimulants. He had become an American citizen, and was a member of the New York Academy of Medicine, the County Medical Society, and the Medical Association of New York; and was the editor of the *Therapeutic Review*. He succeeded in demonstrating the rabies microbe independently. He was greatly interested in psychic phenomena and he wrote a book entitled "Spiritisme: Analyse des Choses," which was translated in English under the title "Psychism: Analysis of Things Existing." He was a voluminous writer. By his will he left $20,000 to the Pasteur Institute, New York. His remains were cremated.

PHILADELPHIA.

Schools for Defective Children.—The Board of Education is considering the feasibility of establishing special schools for children who are mentally defective from organic causes.

Medical Club Reception.—The Medical Club gave a reception Saturday evening, June 9th, to Dr. Abraham Jacobi of New York, Dr. A. Garcelon of Maine, Dr. J. M. Bodine of Louisville, and Drs. Frank Billings and G. H. Simmons of Chicago. Over one hundred of the delegates to the American Medical Association were present.

Jewish Hospital.—The Lucien Moss Home for Incurables was dedicated June 10th. The building is connected with the Hospital proper and is built after the most approved style. Its donor also provided an endowment fund for its support.

Compulsory Vaccination.—The validity of this

law is to be tested by a case now before the courts. A girl of nine years has been kept out of school for two years because her father will not have her vaccinated. He has had recourse to several expedients, among them petitioning the Legislature, but has failed. *Seventeen physicians* are among the supporters of the man.

Health Report.—Deaths in the city for the week ending June 9th were 409, a decrease of 10 from the previous week and of 69 from the corresponding week of last year. Contagious diseases: Diphtheria, 82 cases, 15 deaths; scarlet fever, 61 cases, 3 deaths; typhoid fever, 51 cases, 9 deaths.

University Appointments. — The following have been made by the trustees: Dr. J. William White, Rhea Barton Professor of Surgery; Drs. Edward Martin and C. H. Frazier, Clinical Professors of Surgery; Dr. R. M. Pearce, Demonstrator of Pathology; Drs. W. F. Hendrickson and F. H. Howard, Assistant Demonstrators of Pathology.

American Laryngological, Rhinological and Otological Society.—The sixth annual meeting was held at Philadelphia, May 31, June 1 and 2, 1900. In his opening address the President, Dr. D. Braden Kyle, stated that chemical anatomy and pathology are of great importance and will in the future rank with pathological anatomy, etc. Examination of the inflammatory exudate accompanying influenza has convinced him that it differs from ordinary exudate and that there is as distinct an alteration in structure as in diphtheria or other specific infections. This differs according to the age of the patient, prior attacks, etc. Patients complain of a thickening of the mucous membrane after an attack and microscopical examination shows the presence of a peculiar albuminous material not unlike amyloid. This is probably manufactured in the blood as a result of the toxin of the disease. The best anesthetic for operations on the nose or throat is a good anesthetizer. Chloroform and oxygen, given by passing the gas through the chloroform, is probably as good as any anesthetic in use. No therapeutic agent is more abused than is the actual cautery in diseases of the nose and throat.

Dr. N. L. Wilson of Elizabeth, N. J., made a plea for early operation in "Bilateral Abductor Paralysis." Cases were cited showing the importance of doing tracheotomy or intubation before it is too late. Not every case should have operation as soon as seen, but the danger should be stated to the patient and early operation insisted upon. In discussion Dr. J. Solis-Cohn said that two cases had been saved by carrying tubes with them which the physicians inserted as soon as called. He would do a tracheotomy rather than intubation as the latter destroys the voice and the tube may be coughed out at any time, thus leaving the patient in as great danger as before. As to removing the vocal cords, which has been suggested, he would prefer to employ tracheotomy and other methods first, owing to the contraction which always occurs in a circular cicatrix adding a risk to the former procedure.

Dr. Robert C. Myles of New York exhibited an instrument for removing subglottic growths. Owing to slowness of the maker the instrument was not yet complete, but the principle was shown. It works by shoving the cannula down over the loop which grasps the growth, thus aiding in its retention.

Dr. Joseph S. Gibb of Philadelphia read the history of a case of carcinoma of the larynx. Total laryngectomy was done and the patient died the fifth day after, a streptococcic infection being present. The source of infection was not clear, as aseptic technic had been as thorough as possible. In future cases he would advise a preliminary tracheotomy in order to anchor the trachea and prevent tugging, and also to accustom the bronchi and lungs to this method of breathing. In the discussion which followed, the general opinion was that in cases which were well advanced a tracheotomy instead of laryngectomy should be done. This puts the affected part at rest and renders the patient somewhat comfortable until death results from the growth elsewhere. In closing Dr. Gibb stated that perhaps he was not so enthusiastic about laryngectomy since the case detailed had occurred, but that he was rather surprised at the pessimistic views of American surgeons. Something has to be done for these patients and tracheotomy at best gives only temporary relief. He believes it is better to remove the growth and give the patient a chance to recover or else to die in a few days from the operation.

Dr. Bernard Berens of Philadelphia presented a paper upon the internal use of suprarenal extract in nasal hydrorrhea. The patient was a woman who had a profuse discharge from one nostril after an attack of influenza, the flow being constant and amounting to from 16 to 24 ounces in twenty-four hours. Digitalin, atropine, and strychnine were given for their general effect, and various nasal sprays were tried with no improvement. An application of a twenty-per-cent. solution of suprarenal extract did some good. Five-grain tablets of the extract were then given, one every two hours. After the third dose the discharge lessened and soon ceased entirely. The dose was then diminished until one tablet was given three times a day, and, finally, discontinued. In a few weeks the discharge again began slightly, but the exhibition of the extract promptly caused it to cease. A report of the last session of the meeting will be given next week.

CHICAGO.

Training School for Nurses.—Dr. Sarah Hackett Stevenson delivered the address at the graduating exercises of the Mary Thompson Hospital Training School for Nurses. There were seven nurses who had completed the course and received diplomas.

Officers of the Physicians' Club.—The Physi-

cians' Club of Chicago recently held a business meeting and banquet, at which the following officers were elected: Chairman, Dr. William H. Wilder; secretary, Dr. L. Harrison Mettler; treasurer, Dr. L. Blake Baldwin; directors to fill vacancies, Drs. John M. Dodson, M. W. Bacon, and John L. Porter.

Mortality Statistics.—All the principal causes of death, excepting consumption, cancer and nervous diseases, showed reduced figures last week. According to the weekly bulletin of the Health Department, the mortality-rate is the lowest of any week of the year, and, compared with the preceding week, the following causes show the greatest reduction in number of deaths: Bronchitis, pneumonia, Bright's disease, diphtheria, and heart-diseases. The mortality from acute intestinal diseases and typhoid fever remains lower than last year, and the number of deaths from diphtheria was the lowest for months, there being only six deaths from this cause during the week. There was also a marked decrease in the number of deaths from measles, two last week, as against eleven the week previous.

GENERAL.

Tuberculosis in a Sheep.—Parts of a sheep seized in a London slaughter-house recently was the first authenticated case recorded in England of tuberculosis in that animal.

A Correction.—In the abstract of Dr. Woldert's article recently published in our columns, in connection with the American Medical Association meeting, Dr. Woldert was quoted as saying that the Anopheles mosquito is found near the North Pole; the variety of mosquito should have been designated as Culex.

The Xiphopages Twins Separated.—The two sisters, Rosalina and Maria, who were born joined together, a description and illustrations of whom appeared in the MEDICAL NEWS March 5, 1900, have finally been successfully separated by a continuation of the surgical procedure that was begun last winter. In the first operation the osseous structure joining them was cut apart, but the shock was so great that it was not deemed wise to proceed further. The operator was Dr. Alvara Ramos of Rio Janeiro.

Educational Medical Requirements.—At a meeting of the State Medical Council of Pennsylvania, held at Harrisburg June 8th, it was decided that the rule of the Council relative to the preliminary education of applicants for examination before the State Board should not go into effect until September 1st next. This will raise the standard in the educational qualifications and will make it impossible for the Council to recognize the licenses of other States that have not advanced to the same grade. It will also make it necessary to sever the reciprocal relations that now exist between the States of Pennsylvania and New Jersey.

Doctors in a Duel.—It is reported from Paris that on Sunday, June 10th, Dr. Samuel Pozzi, the celebrated obstetrician and gynecologist, fought a duel with swords with Dr. Devilliers. Dr. Pozzi was promptly wounded in the right hand, the sword of his adversary entering for a distance of three cm. beteen the knuckles of the middle and ring fingers. The code of honor was then declared satisfied, the combatants embraced and returned to the city. The little misunderstanding arose from some dispute connected with the management of a club of which Dr. Pozzi is president.

Neurasthenia from Reading Browning.—Professor Benedict, of the Department of Philosophy and Psychology of the University of Cincinnati, announced to his students on May 29th that readings from Browning will be discontinued owing to the great mental strain upon both professor and student. Lighter literature, such as the works of Plato and Aristotle, will be substituted.

The International Medical Congress.—According to instructions from Dr. A. Chauffard, Secretary-General of the XIIIth International Medical Congress, subscriptions to the Congress will not be received after the 15th of July, and the names of subscribers whose subscription is not received before the 15th of June will not appear in the official program. The publications of the Congress will consist of seventeen volumes, one one of which will be sent gratuitously to each subscriber: that is, the volume containing the papers of the Section under which he has inscribed himself. The other sixteen volumes may be purchased at price of 4 francs per volume, or 45 francs for the series.

To Control Consumption.—The Special Committee of the Health Board of Trenton, New Jersey, made recommendations on June 6th for the suppression of tuberculosis, declaring the disease infectious. The health officers are required to disinfect the room and destroy the bedding and clothing of consumptives immediately after death and physicians and hospitals are obliged to report all cases immediately after diagnosis, under a penalty including imprisonment. The department will make bacteriological examinations free of charge.

Amateur Surgeons.—Captain Bratton of the Medical Department at Sogod, Cebu, in the Philippines, has in a report to Surgeon-General Sternberg recommended for future consideration Private Samuel Jones because of his unusual exhibition of skill, judgment and fortitude. A native woman was assaulted by her husband, who cut her in a number of places and by whose violence she sustained compound fractures of the right forearm. In the absence of the regimental surgeon, Private Jones, with the assistance of Private Henry Becker, administered chloroform, and at night, by candle-light, sewed up the incisions in her chest and back. She would not have her arm amputated, so it was dressed antiseptically. Within two days gangrene set in; so

Private Jones amputated the arm by the circular method. The result was entirely successful.

The American Laryngological, Rhinological and Otological Society.—Officers elected for the ensuing year are: President, Dr. Robert C. Myles, New York; secretary, Dr. Wendell C. Phillips, New York; treasurer, Dr. W. H. Daly, Pittsburg; vice-presidents, for the Eastern Section, Dr. W. S. Renner, Buffalo; Southern Section, Dr. J. A. White, Richmond; Middle Section, Dr. N. H. Pierce, Chicago; Western Section, Dr. J. O. McReynolds, Dallas, Texas. The next meeting will be held in New York in May, 1901.

Obituary.—Dr. Melancthon Storrs died at his home at Hartford, Conn., June 9th in the seventy-seventh year of his age. He graduated from Yale Medical School in 1852 and during the Civil War served as a surgeon in the army. Upon his return he settled in Hartford, Conn., where he has since resided and practised. At the International Medical Congress in 1887 he was one of the vice-presidents of the Surgical Section. He gained distinction as a successful operator in the removal of the trifacial nerve and the restoration of cleft palate.—Dr. Eldridge K. Leonard died at his home, Rockville, Conn., June 13th, from blood-poisoning, aged sixty-nine years. Dr. Leonard assisted Dr. Storrs of Hartford, in the removal of an abscess of the liver of a Rockville boy some two weeks ago and and later took charge of the patient. Dr. Storrs died of blood-poisoning from the operation ten days later.—Dr. William Pierson, for nearly half a century one of the leading physicians of the Oranges, in New Jersey, died June 12th. He had been failing in health for about a year, and had an attack of pneumonia in February, from which he never fully rallied. He was the son of Dr. William and Margaret Hillyer Pierson, and was born in Orange, November 20, 1830. He was graduated from the College of Physicians and Surgeons in 1852, and a year later went to Orange to practise. He at once took high rank as a surgeon. He was recording secretary of the New Jersey State Medical Society for many years, and a week ago was elected president of the society. He was a member of the Essex County District Medical Society, of the New Jersey Academy of Medicine, and consulting surgeon of St. Mary's Hospital, Morristown, and of St. Barnabas' and St. Michael's Hospitals, Newark. He was one of the founders of the Orange Memorial Hospital and chief of its medical and surgical staff since its organization.

The Plague.—The progress of the plague at various points throughout the world still continues ominous; new cases are daily reported at Port Said and at Rio de Janeiro. In India the famine and the cholera have joined hands with the plague in its onward march. No new cases have been reported from San Francisco since June 4th. The Oriental population, numbering over twenty thousand, are not only defiantly opposed to quarantine, but are threatening murder to such of their number as have shown sympathy with the health authorities in their efforts to enforce sanitary measures. Open riots have been threatened in attempts to wreak vengeance on a Chinese merchant who had submitted to the Haffkine treatment, and on an undertaker who had conformed to health regulations in delivering bodies for autopsy. The courts have not sustained the Board of Health in arresting a Chinaman who had broken through the quarantine cordon. Various cities throughout the United States have taken warning from the outbreak in San Francisco and are cleaning up and keeping a sharp eye on the Chinese quarters; both New York and Chicago are conspicuous in this respect.

CORRESPONDENCE.

THE PATHOLOGICAL INSTITUTE.

To the Editor of the MEDICAL NEWS:

DEAR SIR: In the struggle over so great a cause as the freedom of research in psychiatric science, we, for our part, can never suffer the issue to be degraded by personalities. If, therefore, here or hereafter we refer to the struggles of the Pathological Institute of the New York State Hospitals or to the State Commission in Lunacy, it is in the vindication of a cause so precious to us that all personal feeling and animosity are set at naught. If this Institute be mentioned, it represents a principle and a cause; if this Commission or its Committee be spoken of, this also embodies an issue.

With our colleagues in the State Hospitals, of which this Institute is the center of scientific research, we confidently trust that there is now no issue. The Hospitals, it is a source of gratification to say, are in accord with the Institute in its endeavor to accomplish scientific investigations. A minor point of discussion at times between us has been the desire and needs of the gentlemen of the Hospitals to have greater facilities for clinical diagnosis and the use of clinical laboratory methods to follow up the condition of the patients. With this desire, we deeply sympathize. They are absolutely necessary to the actual carrying out of hospital practice. This, however, is the duty of interns; it should not occupy the time of men trained and occupied in the solution of scientific problems. The Institute has endeavored as far as possible to overcome this difficulty by giving instruction to members of the staffs of almost every one of our twelve State Hospitals in nearly every department of the Institute, in order that they might turn this knowledge to account in practical clinical work. (The endeavors of the Institute to aid in this manner the Hospitals in their practical clinical work is being set forth in detail in

the fourth annual report—now in press—of the Pathological Institute.)

The following are two protests. The first of these, with the accompanying letter, we handed on the 22d day of May, 1900, to the President of the New York State Commission in Lunacy at the Richmond meeting of the American Medico-Psychological Association, a few hours before he read his paper, "The State of New York *versus* the Pathology of Insanity," which had been announced on the official programs distributed a considerable time before the meeting. We did not submit to the Commission or any of its members the second protest: its purpose may appear in due time and suitable place. Inasmuch as the President of the Commission through indirect channels has secured this second protest and has seen fit to make it public in its incomplete form, we present it here with the names of all the gentlemen who up to the present time have signed it, either directly or by cablegram. Many other gentlemen have signed the first protest since it was handed to the President. [Since this date this protest has been endorsed unanimously by the Section on Nervous and Mental Diseases of the American Medical Association at its annual meeting, June 6, 1900.] These names have not been added, for it may be well to have the document appear just as it was submitted to the President at the Richmond meeting with the accompanying letter.

In view of the fact that but five days' time elapsed in the signing of the protest, and many gentlemen in distant places signed it *ab initio*, either by telegram or without knowledge of the other signatures, it must be held as a rather remarkable expression of sympathy in the struggle for the cause at stake, and would be a recompense for the sacrifices and vicissitudes of this Institute were its doom to be forthwith sealed. And yet such an expression of sympathy is not altogether extraordinary. For the liberty of thought and freedom of research in one of the greatest departments of knowledge is a principle that must endear itself to the hearts of our best thinking men. Disease of the mind is one of the most terrible blights that can befall the human race, and no boon could be more precious to mankind than an effort to add to our power of curing or preventing it, even although the attempt be slight and made in adversity. Hence it is that such attempts should be welcomed rather than opposed and a heavy responsibility must go with the arrest of an organized effort to add a humble share to the progress of psychiatry, an effort builded not without arduous toil and patient struggle.

IRA VAN GIESON.

1 Madison Avenue, New York.
June 6, 1900.

FIRST PROTEST.

NEW YORK, MAY 17, 1900.

Inasmuch as it is well known that the orignial purpose in the foundation of the Pathological Institute of the New York State Hospitals, was the scientific investigation of psychiatry, and that the former attempts of the Hospitals to pursue scientific investigation in the asylum under the direction and control of the Superintendents "produced no results of scientific value in the line of original work." (See Second Annual Report, State Commission in Lunacy, pp. 147—162); and since

We believe that the comprehensive lines of research formulated by the Director of the Institute and his associates are eminently suitable for this purpose and that the work of the Institute is most promising for the progress of psychiatry,

We, the undersigned, therefore deem most unfortunate any effort to interfere with or subvert the scientific work of the Institute, and we furthermore disapprove of any plan to limit the work of the Institute to the Asylums, and put the work of the Institute under the control and direction of Superintendents, and to divert the energies of this research center into routine educational schemes. And, furthermore, we deplore the methods in crippling the scientific activity of the Institute and in depriving it of sufficient maintenance and adequate quarters in the center of the city, by a legislative enactment forbidding the payment of rent.

Accompanying Letter.

New York, May 21, 1900.

Dear Doctor Wise—In view of the recent criticism and opposition to the principles underlying the work of the Institute, we have felt that it would be but fair not to rely merely on our own views as to the value of our work. We have, therefore, taken counsel with a number of leading men both in medicine and psychology. From the opinion of these men we cannot think of any changes which at present would aid us in our work. Therefore, we think we are all the more justified in maintaining our position. But if there are any minor details the following out of which would not interfere with the fundamental principles of our work, we are always glad to accept your suggestions.

Yours very respectfully,
(Signed) Ira Van Gieson.

Second Protest.

In view of the fact that the Pathological Institute of the New York State Hospitals, founded by Dr. Carlos MacDonald in the year 1896, has been carrying on scientific research in Psychiatry on lines of investigation as worked out by Dr. Ira Van Gieson, the Director of the Pathological Institute and his associates, thus helping the further advance of Psychiatry; and in view of the fact that Dr. P. M. Wise, President of the State Commission in Lunacy of the New York State Hospitals, and Dr. Edward Cowles, Superintendent of the McLean Asylum, Chairman of the Committee appointed by the above named Commission in Lunacy, to sit in judgment and pass sentence on the work and principles of the Pathological Institute, have decided and have actually attempted under the plea of paternal guidance and legislative supply of resources, to interfere, subvert and destroy the scientific work of the Pathological Institute, handing it over to the "superintendency" of New York State Asylum superintendents, and putting psychiatric investigation under "their direction and control," according to the old asylum methods, to do as Dr. Wise insists "what the laboratories have always done in the State Hospitals."

Resolved, That we, the undersigned, protest most emphatically against such a ruthless act of subverting and destroying a scientific institute of great promise for the science of psychiatry, and condemn the interference with the scientific research work of the Pathological Institute, and protest against the crippling of its methods and principles of scientific investigation, either by forcing it to labor in the old pathways of asylum routine or to become the "handmaid," as the Commitee puts it, of asylum men working at the will and command of asylum superintendents, or to divert its energies into educational schemes; and that we sustain the Patho-

logical Institute along its present lines of organization, and principles and research.

THE ATTITUDE OF THE STATE COMMISSION IN LUNACY TOWARD THE PATHOLOGICAL INSTITUTE.

To the Editor of the MEDICAL NEWS:

DEAR SIR:—I find, associated with the names of four other physicians, my own cited in the paper published in your issue of last Saturday, attacking the Pathological Institute of the New York State Hospitals and in close proximity to charges of insincerity and duplicity. It is difficult to ascertain, in the mass of diatribe and innuendo which that unfortunate institution has evoked from Dr. P. M. Wise, at what persons these charges are especially aimed. Nor would I under ordinary circumstances find it necessary to defend myself against such charges, were they directed at myself. But, inasmuch as Dr. Wise additionally implies some lack of consistency and courage on the part of those connected with a petition mentioned as having been signed by us, I ask you to grant me space for a correction of such and similar false impressions derivable from the Doctor's remarkable paper. To others I leave it to find a proper characterization for Dr. Wise's procedure of publishing a petition prior to the completion of its list of signatures; as I also leave it to those who prompted a change in its wording to explain the reasons for such. Having had nothing to do with the original framing or later changes, I limit myself to declaring that I signed both petitions with cheerful alacrity, and would not have been deterred from so doing had either been expressed even more emphatically than the first. For example, I would have signed it if it had incorporated a prayer to the Governor for the removal from office of the present medical member of the Commission in Lunacy. Such a petition would speedily obtain more than the five signatures which it is the evident intent to pillory as those of isolated unfortunates too reckless to weigh the charges they endorsed, or too careless to have read over what they were asked to subscribe. Those signing a petition of the nature I suggest would find ample grounds in the record of an official who, without possessing any ascertainable qualifications for his high office, has made it the center of a pernicious activity, and utilized it to betray the interests of a profession to which—nominally at least—he himself belongs. Should the readers of the MEDICAL NEWS feel interested in a relation of the circumstances occurring after Dr. Wise took office, on which this statement rests, I shall feel justified in occupying further and more space than I venture at present to ask for. In the same connection I may be able to convince our colleagues that if the charge of insincerity be applicable anywhere, it is to the plea of economy when advanced by the critic of the Pathological Institute.

More problematical even than the reasons for the Commissioner's economical solicitude, appears his championship of interests in connection with psychiatry of any scientific character whatever, since the basis on which an estimate of his qualifications in this respect could be made is not available. However, this is not a very important question, for it is quite evident from the Doctor's paper that the more earnest his interests, the more meddlesome and demoralizing would his supervision of the work of the Pathological Institute prove. I refer to the statements about the work done formerly at one of our State Institutions, and which I proved to be of a misleading character (sustained therein by all authorities at home and abroad who have touched on related questions) and showed also that the results had been diverted and distorted for "business" purposes of a quasi medico-legal nature.

It had been Dr. Wise's duty to familiarize himself with the real status of the work done at Utica. It surely had been easy for him to do so. If I err not, he was himself in a position to have familiarized himself with that work, and at the very least ought to have become conversant with the real sources of its failure. He might have learned through whom the special pathologist had been appointed, and by whom he was sustained and kept in place in the face of overwhelming criticism. He would not then have presented a petition signed by all or nearly all the Superintendents under his thumb—among whom are most estimable practical alienists and several men of too much intellectual breadth to have been spontaneously overanxious to have signed that document, had they had certain knowledge which was not within momentary reach. On the contrary, he would in all consistency have been compelled to select one of their predecessors as a terrible example, illustrating the

fallacy of his position and the fallacy of a petition advocating a direct personal control, by the signers of the latter. The work at Utica failed under the domineering influence of the most autocratic superintendent this State has known and under a pathologist maintained in place by him; for as completely was Theodore Deecke the instrument of Dr. John P. Gray, as one man ever has been of another man. Does Dr. Wise wish to use the Institute in like manner? Dr. Wise, by the way, designates that unfortunate pathologist as "a philosopher not a physician." What Dr. Wise intends by this discrimination I fail even to guess. I venture to suggest, however, that a very little of the article commonly regarded as philosophy, nay a modicum of much-abused (not a little so by Dr. Wise) common sense, would have been of service to Theodore Deecke's master, who *alone* was responsible for absurdly interpreting artificial precipitates—as proving "mania and melancholia" to be "manifestations of one and the same diathesis," because manufactured by one and the same erroneous method, by one and the same mistaking pathologist, in one and the same asylum laboratory.

Here was Dr. Wise's ideal of the clinician stepping directly from the ward filled by living clinical pictures to the microscope under which had been placed the prepared section from the deceased subjects who had in life presented such pictures. What was the result? Read the comments of the best critics of the day; "strange views" is the most complimentary allusion they made!

The gracious courtesy with which Dr. Wise states that Dr. Van Gieson may be of unsound mind and even suggests that his case would fill a special clinical pigeon-hole would justify reciprocal courtesies by Dr. Van Gieson, say, in the way of an analysis of narrow characters in places too wide for them, or of red tape-fed barnacles, jealous of their little all; official prerogative by letter of law. But, possibly, Dr. Van Gieson believes such attacks as Dr. Wise makes to leave the man making them in too hopeless a state to render any stimulus of counterirritant useful. For Dr. Wise is in this alternative position: Either he believes what he says, and that Dr. Van Gieson is mentally diseased; in which case he exemplifies the notions of philanthropy and charity to the insane acquirable at the largest State Asylum (Dr. Wise served at the Willard State Hospital) by triumphantly taunting a thus disabled adversary with his great misfortune; or he casts a stigma knowing the statement to be untrue. I prefer to pause here. The reader may draw his own conclusions. Mine may be inferred from the fact that I fail to discover any signs of mental disorder in the assailed pathologist, and that I do not consider it probable that one of his performing power is likely to be affected with a latent taint that Dr. Wise, and Dr. Wise alone, were able to discover. I say this seriously, because it is a serious charge made by the medical member of the Commission of whom the insane are the official wards, and made not in an unguarded moment, nor flippantly, but in a widely-circulated periodical, perused by reflective readers, and in the course of a discussion inaugurated in a paper read before the National Association of asylum physicians. I may, however, express a reflection which must occur to your readers, that if the work at the Pathological Institute is of a high character, as Dr. Wise admits in another place—work which has been and is mainly planned by Van Gieson—it were desirable for Dr. Wise to no longer withhold the name of the clinical form of that investigator's mental "symptom-group"; I should like to know where the article may be obtained. If inoculable I know a few who might profit by the publication of Dr. Wise's secret!

There is one point in Dr. Wise's exposition of the situation in which he is accurate; it relates not to any scientific question, but to that "letter of the law" so resourceful to political and legal combatants not necessarily of the highest order. It is true that the Commission has the directing power over the Institute. But Dr. Wise is mistaken if he believes the interpretation of this clause—which was undoubtedly intended as what it appears to the reasonable, *i. e.*, a courtesy to authority—to rest with him. Science never flourished in a Procrustean bed of the Wise kind; it is with the masters that the interpretation rests, not with those who have not even served their apprenticeship. It is difficult to define a control which is not all control, but there is a practical illustration available which may be taken as involving precedent and principle.

By letter of the law, our President is Commander-in-Chief of our land and sea forces in time of war. But does the President interfere in the conduct of campaigns, hamper admirals by counterorders, disband this brigade in the field, remove that officer while under fire, call truces or break them without previous knowledge and request of those directly involved? If he did, he would justify such a procedure as rumor attributed to Admiral Dewey, namely, his intentionally breaking or avoiding his cable connections with a naval department which it was apprehended might embarrass him by blundering interference in a position sufficiently critical without such Similarly need Dr. Van Gieson be declared guilty of insubordination when an important interest is jeopardized by ill-timed and inexpert meddling.

No doubt sticklers for the "letter of the law" will justify the claim of Dr. Wise to order special work, even of the "bed-bug exterminator" analysis kind, to which your recent editorial refers But it would so stultify itself thereby that the aroused sentiment of the profession would drive it to its proper domain of burcaucratic control. When I reflect on the high plane of the work begun and projected in a pure conception of that correlation of sciences so puzzling to Dr. Wise, and learn that through medical politics—the worst form of politics—that work is hampered

and the workers dispirited. I feel an indignation like that of him who sees a clumsy foot crush a delicate mechanism, a rude hand defile a work of art.

I trust your journal will continue to sustain the Institute to whose director it is no reproach that in the kind of warfare forced on him in so ignoble a spirit he does not display the wirepulling adroitness possessed in the opposition. Science and that grade of cunning required in the latter art are rarely, if ever, united in the same "symptom-group."

In conclusion, permit me to anticipate surmises as to possible personal interest in the Pathological Institute of the New York State Hospitals. How absolutely little I have had prior to this date may be judged from the fact that I have never been inside of it. This admission in turn may be utilized as a proof of my unfitness as a critic. But it can be so utilized by those who are unaware that a judgment may rest on the perusal of published results and by such alone.

It is true that the Institute has not yet solved the pathological problems of insanity. It is conceivable that neither it nor any contemporary laboratory may entirely succeed. But it is certainly working in the direction in which all legitimate research seems to be moving. Mention the name of Van Gieson at American or European laboratories, and it will be recognized. Possibly the aptly-worded "methods not matter" criticism, which is made use of by the Wise investigating committee, may be here interjected. Without disputing it, though indeed it is most disputable, it is not well to devise and practice reliable "methods" before manufacturing such "matter" as the "alienists" of the school of which Dr. Wise was a pupil foisted on us?

E. C. SPITZKA.

New York, June 5, 1900.

OUR LONDON LETTER.

[From Our Special Correspondent.]

LONDON, June 7, 1900.

THE INTERNATIONAL CONGRESS OF GYNECOLOGY AND OBSTETRICS — BOYCOTT BY THE LONDON TEACHERS—CASUALTIES IN THE SOUTH AFRICAN WAR—SNARES OF INSURANCE COMPANIES FOR MEDICAL MEN—THE USE OF PRESERVATIVES IN FOOD—LECTURE BY PROFESSOR DEWAR ON "A CENTURY OF CHEMISTRY"—FLORENCE NIGHTINGALE'S EIGHTIETH BIRTHDAY—WANT OF CONSULTING PHYSICIANS IN THE SOUTH AFRICAN WAR—LATENCY OF TUBERCLE BACILLI IN THE TISSUES PRODUCING A RELAPSE OF LUPUS MANY YEARS AFTER RECOVERY.

THE success of the forthcoming International Congress of Gynecology and Obstetrics is seriously threatened by an extraordinary and unanimous resolution of the teachers of gynecology and obstetrics to take no part in it on the grounds that those who issued the invitation have assumed a representative position to which they are not entitled. In reply to a letter addressed to the medical journals making public this resolution, Dr. W. J. Smyly, President of the British Gynecological Society, Dr. MacNaughton-Jones, Chairman of the Organization Committee of the Congress, and Dr. A. E. Giles, Honorary Secretary of the British Gynecological Society and of the Organization Committee of the Congress, explain that the invitation was issued by the British Gynecological Society which is not concerned to defend itself against the opinion of the objectors. They point out that if the names of the Fellows of the Society are not sufficient to correct the opinion that they have wrongly assumed a representative position, the fact that the Permanent Committee of the International Congress of Gynecology and Obstetrics requested the Society to issue the invitation shows that its representative character is recognized abroad. Accordingly, Dr. Robert Barnes, Honorary President of the British Gynecological Society, gave the invitation at Amsterdam in 1899. The manner in which the president of the forthcoming Congress, Prof. A. R. Simpson of Edinburgh, was elected is also objected to. To this the officers of the Gynecological reply that he was nominated at a meeting of the Council on whom the duty necessarily devolved. This controversy is much to be deprecated and no doubt behind it are motives which do not appear on the surface.

According to official returns the total casualties of the British forces in South Africa up to May 12th were 20,108. These are composed as follows—Killed in action, 2322; wounded, 10,701; missing and prisoners, 4549; deaths from disease, 2492; accidental deaths, 54. The sick now in hospital are not included in this list. Of those enumerated as wounded a large percentage have returned to duty. The deaths from disease average 300 a week and form nearly 50 per cent. of the total mortality, so that the number of men in hospital must be very large.

The reputation of the average medical practitioner in this country as a man of business is notoriously bad and he, therefore, easily falls a prey to designing persons. A bait is now being held out to catch unwary ones by a new insurance company. On condition of taking up shares they are appointed medical examiners at large fees. For an insurance of £100, £1.1 is to be paid; for larger sums the amount is greater, rising to £3.3 for £500. When these alluring terms have had due effect it is explained that the doctor is expected to take up shares "which are payable in full on application." Thus, cash would be parted with at once to a company, which does not even profess on its own forms to be registered, in the shadowy hope of professional fees.

At the meeting of the Departmental Committee appointed by the President of the Local Government Board to inquire into the use of preservatives and coloring matters in food, Sir T. Lauder Brunton gave very important evidence. He has come to the conclusion that it is almost impossible to prevent the use of preservatives, but that their use should be strictly regulated. If

preservatives are not used there is a risk of eating decomposing food. The presence, nature and proportion of the preservative in each article of food should be announced by label or otherwise. Dr. G. Vivian Poore pointed out that besides the positive harmfulness of certain preservatives the negative side of the question was most important, as there ought to be to risk of mistaking fresh for preserved food.

At the Royal Institution Prof. Dewar gave the fourth and last of his course of lectures on "A Century of Chemistry in the Royal Institution." Continuing his account of Faraday's observations, he described the second stage of that investigator's work in the liquefaction of gases. He discovered benzene, which forms the basis of the whole coal-tar industry. His work in organic chemistry received great extension at the hands of Sir Edward Frankland, his successor, the scope and variety of whose researches made him second to none as an experimenter of the modern type. His work was largely identified with organic synthesis and he made elaborate researches on water-supply and on the manufacture of coal-gas. Referring to Dr. Gladstone he said that his name would be remembered for his study of the relation between the refractive index of bodies and their density.

Florence Nightingale, who won world-wide fame by her services to the sick and wounded in the Crimean War and was the pioneer of skilled nursing, has just celebrated her eightieth birthday. She received numberless congratulations, thoughtful gifts and flowers. None was more prized by her than a basket of choice blossoms sent by no fewer than 650 former "Nightingale nurses" from St. Thomas' Hospital and the Notting-Hill Infirmary—nurses trained for hospital and poor-law work through her great gift of £50,000, which a people's gratitude asked her to accept on her return from the Crimea. Accompanying this offering was an album containing a letter of congratulation, expressing gratitude for the benefits which she had conferred on the signatories by creating a noble calling for women. Miss Gordon, the matron of St. Thomas' Hospital and Superintendent of the Nightingale School, made the presentation. Amongst those who signed the latter were two of the original probationers of the School who joined forty years ago, and matrons and nurses from Australia, America, the seat of war, West Africa, India, Canada, Russia, and all parts of the world.

Speaking at the dinner of the Pharmaceutical Society, Sir James Crichton Browne expressed regret that, while a number of eminent consulting surgeons had been sent to the seat of war, a few eminent physicians had not been sent also. The long lists of deaths from enteric fever were nearly equal to those from wounds. The deaths from that disease were mounting up daily out of all proportion to the strictly military casualties which, thanks to Lord Roberts' splendid strategy, were now trifling. Every death from enteric fever must represent four cases of disease which must be causing an enormous disability in the forces. Enteric fever has always been prevalent in South Africa, but the occurrence of the disease at so many Stations, some of them in typically healthy situations, suggested careful inquiry so that precautions might be taken. To say that nothing could be done in the medical treatment was fatalistic folly. There was no disease in which skilled supervision could do more to prevent death and promote recovery.

At the Polyclinic Mr. Jonathan Hutchinson showed an interesting case illustrating the possible latency of lupus germ-cells. The patient was a young woman, aged twenty-nine, who was treated for lupus vulgaris eight years ago. After repeated applications of nitric acid the lupus was completely cured, nothing remaining but a thin, pale scar. This condition persisted for seven years; then two minute spots of lupus-growth appeared at the edge of the scar. This case shows that the tubercle bacilli of lupus may remain absolutely latent for many years. Mr. Hutchinson has observed another similar case in which, after the cure of a lupus-patch by cauterization, the scar remained healthy for thirty years; then a relapse occurred. It is impossible to suppose that in such cases a fresh infection of the subject has taken place, for the recurrence is always close to the scar of the original disease. The bacillus must remain in symbiotic union with the tissues without showing any activity until the vitality of the part, having been lowered by age, illness, or exposure to cold, is liable again to manifest signs of activity.

British.

THE WOUNDED IN THE PRESENT WAR—CHANGES IN THE BLOOD IN DISEASE—UTERINE FIBROMATA—LAMINECTOMY FOR PARALYSIS.

At the May 8th meeting of the Royal Medical Society, Treves described the wounds as much less extensive and fatal than with the old arms. Vital parts were often pierced without fatal results. Clothing was much less often carried into the body than formerly. Cases of nerve-trunks and bone-shafts pierced, as with a gimlet, with a minimum amount of damage were cited. The bullets from Mauser rifles were retained in 20 per cent. Hemorrhage, except in short range wounds, were rare and usually easily controlled by the soldiers. This was not the case in abdominal wounds at short range. Fractures were more commonly transverse than oblique as formerly, did well if left for a time in the field-hospital, but suffered often from the long transportation necessary. The more serious bone lesions appeared to be in the head of the humerus and about the lower end of the fibula. Injuries of the head often made wonderful recoveries but usually required prompt operation. The abdominal cases left alone recovered in 60 per cent.: operated on, fewer recovered. The shock appeared as the chief symp-

tom and long transportation as the least favorable condition. The intestinal wounds were usually minute and the impact paralyzed peristalsis. Indications for prompt abdominal operation were as follows: (1) When the case was seen within seven hours; (2) when the transport had been short and easy; (3) when the wound was antero-posterior, above the umbilicus, and the bullet had escaped; (4) when there was extensive hemorrhage; (5) sometimes when the wound was below the umbilicus with hemorrhage and escape of the ball. Contraindications: (1) When the case was not seen within seven hours; (2) when the transport had been long and arduous; (3) when the wound was transverse or oblique and above the umbilicus; (4) when the ball was retained; (5) when the liver and right kidney were involved, because these usually recovered; (6) when the wounds were below the umbilicus, for the same reason.

Surgeon-General Jameson concurred with Mr. Treves in the statement that the field-hospital should be as near the firing line as possible to avoid the damage of long arduous transportation.

At the meeting of the Pathological Society of London, May 1st, WRIGHT in discussing blood-changes said mere enumeration of red and white cells does little good. Bacteria are more important, but they occur in few diseases. The discovery of nucleated cells, myelocytes and normoblasts in pernicious anemia is important, but after all the present methods of blood-examination are not of definite diagnostic value apart from other symptoms. Some years ago he thought he had found the cause for hemophilia in an alteration in the number of polynuclear white cells in children. Later he abandoned his conclusions on proving that 40 per cent. of all children had the same condition. The rapidity and completeness of coagulability were new and important data. In hemopysis and aneurism if we could raise them much good could be done. Starvation will not do it. Hearty eating often does. Next came estimates of the lime salts as an index of the coagulability. Increasing the salt hastens the rate. The number of white cells also has a similar effect, realized by giving thymus-gland tabloids. Alkalinity is another important factor, as is the amount of agglutinin. Much of it was favorable for the course and prognosis in typhoid and some other fevers.

Dr. Lorrain Smith said he had measured the total quantity of blood, of oxygenating power, and total amount of hemoglobin per unit of weight to the individual. The study of anemia on this method showed that there were two types —that of chlorosis in which the total oxygenating power is normal, while the volume is increased, and that of anemia due to hemorrhage, in which there is really loss of hemoglobin.

Drysdale pointed out that the red and white cells vary independently of each other. Hence there is little value in making counts only of either or both.

At the meeting of the Obstetrical Society of London, May 2d, WILSON claimed both a casual and often a causal relation between fibromata uteri and organic disease of the heart. The cardiac lesion may be caused by the uterine or depend on the same factors. Circulatory pressure-effects might directly damage the heart or interference with the ureters might set up renal, then cardiac, trouble. Anemia due to menorrhagia might be a source of disease. Cardiac hypertrophy occurs in pregnancy and might in fibroids and by the persistence of the trouble go on to dilation. The presence of such cardiac lesions contraindicates ergot, but usually strongly indicates operation at an early date to prevent the cardiac element from becoming fixed.

At the Edinburgh Medico-Chirurgical Society, May 2d, COTTERILL showed a patient on whom he had done laminectomy for paralysis of two years' duration. Caries had begun when the patient was thirty-six years of age; complete paralysis, both motor and sensory, was present as far as the anterior superior iliac spine; the deep reflexes were exaggerated, the superficial ones various; two large bedsores were present on the buttocks; cystitis and incontinence of the bladder and rectum appeared. The laminæ and spines of the eighth, ninth and tenth dorsal vertebræ were removed. Pressure due to exostoses had narrowed the canal to the diameter of a slate pencil. The lumen was restored. Sixteen days after operation all symptoms began to improve, sensation, motion, continence returned and cystitis disappeared. One year after it he was walking with canes and still gaining.

SOCIETY PROCEEDINGS

AMERICAN MEDICAL ASSOCIATION.

Fifty-first Annual Meeting, Held at Atlantic City, N. J., June 5-8, 1900.

SECTION ON DISEASES OF CHILDREN.

(Continued from page 944.)

SECOND DAY—JUNE 6TH.

Infant-Feeding.—The morning session was devoted to the consideration of infant-feeding and to diseases of the digestive tract.

Dr. A. L. Sherman of New York demonstrated a "home milk modifier." This consists of a graduated glass measure having seven sides or panels. One panel is graduted for ounces, the other six have various percentage formulæ. Nothing is more accurate except laboratory modification, and the simplicity of the method is its valuable point.

Typhilitis, and Appendicitis in Children.—Dr. J. N. Byrne of New York read this paper. Few cases of typhlitis or perityphlitis are primary. Inflammation of the appendix is always accompanied by more or less inflammation of the peri-

toneum. Foreign bodies do not play the rôle in the causation of appendicitis that they were formerly supposed to do. The infrequency of stricture of the appendix before the twentieth year of age raises the question of its later frequency being due to inflammation or to physiological retrograde changes in the organ. Evidence points to the latter. Many cases of intestinal trouble, "biliousness," etc., are due to disease of the appendix.

Milk in Berlin Hospitals.—Dr. Louis Fischer read a paper on "Milk-supply and Control at the Kaiserin Friedrich Hospital by Drs. Adolph Baginsky and Paul Sommerfeld, of Berlin." The arrangement of the stables, care and feeding of the cows, etc., was given in detail. The hospital now has a stable of its own as well as controlling several milk-dealers. Reliance is placed on chemical examination of the milk as a test. The cows that are fed on dry fodder, potatoes, slops, etc., are apt to cause diarrhea and milk from such cows has a toxic effect upon the children using it. The milk is filtered and put in cans in the dairy adjoining, drivers and other employees not cleansed for the purpose are not allowed to enter this building. All cows are tested by tuberculin. At the hospital the sole duty of one maid is to prepare the milk for the infants. Both the full and mixed milks used are sterilized in bottles for thirty minutes at a temperature of 100° to 101° C. The writers do not approve of the criticism against the sterilization of milk. If Barlow's disease comes from sterilized milk it is from that which has been kept for a length of time in storage. Pure milk does not agree with dyspeptic children and dilution is absolutely necessary.

Infant-Feeding.—This was the subject presented by Dr. Alexander McAllister of Camden, N. J. Our present knowledge of chemistry has failed to produce a synthetic breast-milk, advance being needed in this direction. A plea was made for a closer adherence to Nature's methods. Two conditions must be met—an alarming disinclination of mothers to nurse their babies, and the clamor for supremacy in the sale of artificial foods. Babies nursed by mothers may or may not be as fat as those reared artificially but they are robust. Cow's milk furnishes many chances for infection. If the mother cannot wholly nourish the child, partial breast-feeding is of great value even if only once in twenty-four hours. Before giving up and adopting other means of feeding, stimulate the mother's secretion as much as possible, remembering that nutritious food is a better galactagogue than drugs. When cow's milk must be used, modification is *necessary* but clean milk is *imperative*. Attention to the getting of clean milk is much more valuable than copying various formulæ for modifying it.

Infant-Feeding: Accidents and Incidents.—Dr. W. P. Northrup of New York presented this paper. He said accidents may arise from the very exactness used in the feeding. The modifying of milk for the use of infants places a great responsibility upon the physician, and he must remember this when adopting his formulæ. A case of scurvy followed by rickets was detailed. This was due to the formula not being changed for months at a time. He thinks that many babies are given milk which is behind their age in its strength. His ambition is to gradually increase until full milk is used at eight to ten months of age. Fat, sugar, and proteids should be advanced together.

The discussion on infant-feeding was opened by Dr. Henry D. Chapin of New York. He stated that what was gained biologically was lost chemically in the sterilization of milk. In hospital use he has abandoned sterilizing, as the infants fed on such milk invariably get thinner. Percentage feeding has not solved the question and physicians have gone too far in its use. The most important question is that of getting the fats and proteids in a form which can be digested by the infant. The conclusion that the less manipulation given cow's milk the better is the result experienced. While laboratory feeding is an advance, its disadvantage is the excessive amount of manipulation involved. After being separated the fine emulsion can not again be obtained by mixing. The plan now used by Dr. Chapin is as follows: He insists on the milk being bottled at the farm and delivered to the family in the original bottle. If proper cleanliness is observed at the farm (and this should be looked after) the milk is started absolutely clean and is not manipulated. The milk is allowed to stand in quart bottles until the cream rises, nine-tenth of the butter fat coming to the top. The distinct line of the cream should be looked for to prove that no milk has been put in since the bottle was first filled. By means of a cylindrical ounce dipper on a long handle the contents of the bottle are then removed, beginning at the top. The first 9 ounces from the top of a quart bottle contains 12 per cent. butter fat, 4 per cent. proteids, and 4 per cent. sugar. The first 15 ounces contains 8 per cent. butter fat and the same percentage of proteids and sugar. Many samples have been assayed and give the above proportion with great uniformity. In this way but little manipulation of the milk is required and a percentage which is accurate enough is obtained. As the mother can do this, it is of great importance. Rules have been made too abstruse, a professor of physics and chemistry and a laboratory being necessary to carry them out. Hence, mothers get disgusted and buy artificial foods. After a trial of all diluents gruels are preferred. These are dextrinized in nearly all cases. Instead of saying, 'so much fat' should be given, watch the stools. Attention has been given to the wrong end of the baby.

Dr. Victor C. Vaughan agreed that the very fine modifications of milk are often unnecessary and even unjustifiable. Sterilization and Pasteurization alter milk to some extent. The chief proteid changed by a high temperature is nucleo-albumose. The point is not definite; at 158° F.

it is little changed but at 160 F. the change is quite marked. Diarrhea is often due to failure in sterilization. The colon bacillus is variable in virulence. Again, the bacillus is destroyed but its toxin is not, a temperature of 356 F. having no effect on the toxicity of some samples. Hence, no amount of sterilizing will render such milk fit for infant-feeding.

Dr. William L. Stowell stated that bad results were at times due to a failure to distinguish between the therapeutic effect and the nutritional value of modified milk. The former may be kept up and the latter lost sight of in practice. He prefers to use whole milk when the infant is six month of age. Attention was called to two points: (1) Infants can and will digest large quantities of casein; (2) many physicians do not modify milk rapidly enough to keep up with the age of the child.

Dr. A. Jacobi said that if any one had come to the session with the impression that he could learn positively how to feed children he must be disappointed, for different advices had been given by the speaker. He advised each physician to use his own brains, as it is wonderful how handy brains are in the practice of medicine. Most practitioners are diluting with cereals and this is the best method. Nine out of ten babies cannot digest pure milk. When milk is once separated it can never be made into milk again. Mother's milk is not exactly the same at all times yet infants thrive on it. Hence, there is some mistake in the statement that modified milk must have just such a percentage on such a day. Nature is more generous than are doctors' theories. A normal baby will pass out undigested material when fed on its mother's milk. Good has been done by boiling, sterilizing, etc., but we are overdoing our theories.

Dr. J. P. C. Griffith believes that sterilized milk is capable of producing scurvy, yet he believes in the process under certain circumstances. He has also seen four cases of scurvy due to a faulty use of laboratory milk, but he is a great believer in the use of laboratory milk. Judgment must be used.

Dr. Henry Koplik said that a distinction must be made between healthy children and those that are not quite well. Milk is easily contaminated and mothers should be taught to keep it clean. He believes it is, and always will be, a human impossibility to get cow's milk that is absolutely clean. For a diluent he does not use cereals in health but water. If the child be sick an effort should be made to use something that will agree with it.

Gastro-intestinal Hemorrhage in New-Born.—Dr. E. H. Small of Pittsburg reported a case of this condition. The delivery of the child was by forceps. When thirty-four hours old there was a discharge of blood from the mouth and rectum, and at intervals of a few hours three other discharges from the rectum occurred. The nature of the affection was discussed, the fact that more cases occur in institutions than in private practice pointing to an infection as the cause. There are probably changes in the blood or vessels or both. The differential points between this affection and hemophilia were indicated.

Stools in Diarrhea of Infants.—The following types were discussed, the green, brown or muddy, leaden, whitish-gray, mucous, and the dry pasty. In the treatment, hygiene is of vital importance. In addition to this, treatment falls under three heads: Elimination, disinfection and feeding.

Contagious Diseases.—This, the regular topic for the afternoon, was then taken up. "Shall Children be Kept from Measles and Exanthemata" was the subject of the paper of Dr. C. F. Wahrer of Fort Madison, Iowa. It is best to quarantine against some diseases, because their mortality is great and the tendency to acquire them diminishes with age. Such are scarlatina, diphtheria, variola, pertussis, etc. In the case of measles the disease is less severe in childhood and more severe after puberty. Epidemics among adults in camps, mines, etc., are productive of great harm. Hence, it is not always best to keep children from being exposed to the disease. It should be guarded against in hospitals, crowded tenements, etc. There is no good reason why healthy children above two years of age should not be exposed.

In the discussion Dr. Griffith did not agree with this view. In one large foreign hospital the deaths from measles were more than from either diphtheria or scarlet fever.

Dr. L. Fisher would not allow children to catch measles if he could prevent it. He finds serious complications, as otitis media and empyema, to be too common to warrant this. Laryngeal stenosis is a complication that is fatal in many cases: 20 of 25 cases he intubated ended in death.

Dr. J. F. Schamberg stated that the mortality from measles was greater than was generally supposed. In Philadelphia during the past year it was greater than the mortality from diphtheria or scarlet fever.

Roetheln.—Dr. Henry Koplik of New York City read this paper. He considered it from the standpoint of a distinct affection apart from measles and scarlatina, and its differentiation from these exanthemata. Rötheln has been doubted as an entity by some writers, but it can be proven to be such. It resembles measles and is often mistaken for that disease. The eruption appears on the face as a papular rash of deep rose color, as a rule discrete, with crescentic outline. It spreads rapidly over the body, its appearance on the buttocks and thighs being regarded of diagnostic importance. In from a few hours to a day it fades. A real desquamation has never been established by Dr. Koplik. Unlike measles, Rötheln is not a disease of the mucous membranes, and the cough, coryza, etc., of measles are never seen. The conjunctiva is injected as in grip, but there is no photophobia. Children do not generally complain of the tonsils, which are injected, but adults do. As to the

soft and hard palates, streaks and spots of eruption have been reported as occurring in these locations during the disease. He has also observed this in epidemics, but the point emphasized is that these spots are absolutely not characteristic of Rötheln and hence of no diagnostic importance. The red spots with bluish-white center characteristic of measles are absent so the buccal mucous membrane is of negative diagnostic value. There may not be any temperature-rise in Rötheln. If there be a rise it is generally at the outset of the disease; whether the eruption be out or not. The temperature may drop while the eruption is still present. A study of the lymph-nodes was made in 12 cases. The glands of the neck, axilla, and groin were distinctly enlarged. In rare cases of measles this also occurs, but so rarely as to make them of diagnostic importance in Rötheln. This enlargement of glands often persists after the eruption has disappeared and sometimes lasts for weeks. The spleen is not enlarged.

In discussing this paper Dr. Griffith said he had repeatedly seen desquamation in cases of Rötheln. He does not find the temperature-chart characteristic, although the glands are enlarged more than in measles; the cervical glands are often enlarged in the latter and are found if looked for.

Dr. Koplik said that he ruled out the cervical glands when making the diagnosis of Rötheln, referring only to those of the axilla and groin which are diagnostic. He has never seen severe complications with the disease. He isolates cases, letting the children run in the street as soon as the rash disappears in summer, but keeping them indoors for a week in the winter.

Scarlet Fever Rash.—Dr. Jay F. Schamberg of Philadelphia gave the results of clinical and pathologic study of this condition with especial reference to its origin and the character of its desquamation. The clinical appearance of the rash of scarlet fever was described as being made up of generalized erythema, punctated spots, "goose-flesh" papules, due to inflammation instead of contraction of the hair-muscles, and miliary vesicles. These vesicles are present in the vast majority, if not all, of the cases of scarlet fever, sometimes being so marked as to suggest some other disease. In some cases the vesicles are not seen with the naked eye, but are found in large numbers by the aid of the microscope. The vesicles appear more often in severe rashes and are more copious in cases of intense eruption. The intensity of desquamation is directly proportionate to the amount of vesiculation present. Too much stress has been placed on desquamation as a diagnostic point in diseases, the process only being the termination of some other stage. The persistence and character of the desquamation is of more importance than is its mere presence. Desquamation is the result of the vesicles pushing off the epidermis. The conclusions reached are: (1) The color of the rash varies in individual cases. Occasionally it is scarlet, but more often a dull red with an element of brown present. (2) The rash consists of punctæ, vesicles, and "goose-flesh" papules. (3) Vesicles are more common than ordinarily supposed. (4) Desquamation begins at the summit of the vesicles and enlarges.

In discussion Dr. Wahrer said that descriptions of rashes were very good, but it is hard to give an idea of them to others. Clinical experience is worth all descriptions and is the only way one could learn to differentiate.

Dr. Schomberg in answer to questions stated that he had examined the glands in 100 cases of scarlet fever and found enlargement to be constant. He has also noticed white spots on the gums in measles, but they occur as well in scarlet fever. He thinks they are really a desquamation of the epithelium which is whitened by infiltration. They are not diagnostic of measles.

Fetal Ichthyosis.—Dr. Annie S. Daniel of New York gave a demonstration of a specimen of this condition with complete pathologic and bacteriologic examinations. The child was born of a healthy Sicilian peasant woman, labor occurring two weeks before it was anticipated. The woman had had four normal pregnancies and one abortion. The child weighed five pounds, cried constantly, could not suckle, and died when twenty-seven hours old. Pathologically the same lesions were present that have been reported by other observers. No cause for the condition could be found.

Fetal and Infantile Typhoid.—Dr. John Lovett Morse of Boston read this paper. It has been proven that the typhoid bacillus can pass through an abnormal, and possibly a normal, placenta, and thus infect the fetus. The lesions in fetal typhoid cases are general rather than local, as might be inferred from the nature of the infection. This being through the blood primarily it is of the nature of a septicemia from the beginning. This septicemia accounts for the large mortality of fetal typhoid. Infection of the fetus does not necessarily follow infection of the mother. The intestine of the fetus is not functionating, hence, the classical lesions of typhoid are not found in it. Regarding infantile typhoid there is no obvious reason why the disease is more rare during the second year, but such is the case. During the first year when the infant is nursed, chances of infection are less, but chances seem greater during the second year when milk is used in large amounts. However, the disease is either uncommon or is unrecognized. It is hard to differentiate between the lesions of enteritis and typhoid. Pathological studies and tests by serum reaction should be carried out in large series of cases to determine the frequency of typhoid in infants. The symptoms are essentially the same as in adults except that they are lighter. The mortality is greater.

In the discussion Dr. J. C. Wilson emphasized the necessity of using the modern methods of research to find the pathological lesions in certain clinical conditions. He finds the mortality

of enteric fever to be decidedly less in children, at least in cases where the symptom-complex justifies the diagnosis of enteric fever. Many cases can be decided only by the application of modern methods of investigation, especially the serum reaction. He recognizes three types of the disease, the fetal, the infantile, and the adult. One difficulty in recognizing the infantile type comes from the fact that this type occurs at times in adults, and the adult type is occasionally found in infants.

Dr. Griffith believes typhoid fever is much more prevalent in infants than is generally thought. The mistake is made in looking for the adult type when the infantile form is different in its symptoms. More cases in infants will be found since the serum reaction has come into use. Infantile typhoid cannot be called a rare disease now. He finds the mortality less than in adults.

Dr. Morse stated that in childhood the mortality was less than in adults, but that in infants under two years of age statistics and his own experience showed a higher mortality. Present data as to the frequency of the disease in infants are unreliable. Research needs to be made.

THIRD DAY—JUNE 7TH.

Diseases of the Blood and Circulation.—Dr. Leopold F. Haas of New York City reported two cases of diabetes mellitus in children. The patients were a girl of nine and her brother aged five years. Both had adenoids and enlarged tonsils. There was a family history of tuberculosis on both the paternal and maternal sides. The girl had peliosis rheumatica in addition to the diabetes. The boy had been run over by a bicycle before the disease appeared. A possible etiological relation between peliosis rheumatica and diabetes mellitus was suggested. The history of tuberculosis was also considered significant.

In the discussion Dr. Stein stated that the pathogenesis of the disease was not so obscure as supposed, it being an affection of the nervous system, especially of the brain. It has nothing to do with diabetes mellitus in older persons. Operative procedure is the best treatment, spinal puncture, trephining, etc.

Dr. Lautenbach stated that he hears adenoids mentioned in every Section. They seem to be indicative of some systemic condition. They might serve a useful purpose in diagnosis, etc., if we only knew what they meant.

Scorbutus.—Dr. Henry E. Tuley of Louisville, Ky., read a paper entitled "Purpura Hemorrhagica or Scorbutus: A Clinical Sketch." The case was clinically a typical one of scorbutus, but also had symptoms of purpura hemorrhagica. The child had been fed at the table and could hardly have had true scurvy. He thinks the term purpura hemorrhagica should not be used as the affection so-called is a modified form of scorbutus.

Dr. Griffith, in discussing the paper, said that purpura is just such a word as jaundice and the diseases in which it occurs shade into each other. Sometimes the rash is purpuric; again it is erythematous or urticarial.

Value of Blood-Examinations for Diagnostic Purposes.—This was the subject presented by Dr. J. Brandeis of New York. Diseases were divided into three classes, *viz.*: (1) Those in which blood-examination is essential to a diagnosis; (2) those in which it is an aid to diagnosis; (3) those in which it helps determine the prognosis.

In the discussion Dr. Morse stated that many diseases had been given which were not common to children and the same conclusions would not answer owing to the difference of blood-diseases in children. The different forms of corpuscles, especially the nucleated, do not have the serious significance in children that they do in adults. Leucocytosis also occurs much more easily in children. In cases of serous pleurisy in adults he has found no leucocytosis and thinks the sign is of no value.

Iodine Reaction.—Dr. Louis Fischer read for Dr. S. Weiss of Vienna a paper on the "Differential Diagnosis Between Abdominal Typhoid and Appendicitis, by Means of Iodine Reaction: Report of Case." The solution used is Ehrlich's iodine gum solution:

℞ Iodi sublim. 1.0
Kali jodati. 3.0
Aqua distill. 100.0
Gummi Arab. q. s. ad consistentiam syruposam.

A drop of blood is pressed between cover-glasses, to get as thin a film as possible, and allowed to dry in the air. A drop of the solution is then added to the slide and the specimen is ready for examination. The blood from a healthy person gives the following reaction: The red corpuscles stain a dark-yellowish color, the leucocytes being a lighter color and their nuclei appearing as lemon-colored, very glossy bodies. Normal blood also contains brown granules (extracellular glycogen). If suppuration be present in the body the blood gives a different reaction. The extracellular glycogen is considerably increased. The leucocytes assume a brownish hue of varying intensity, being a dark reddish-brown in some cases. This coloration may be general or in fine or coarse granules which are plainly distinguishable from the remaining yellow cell-bodies. The probability of a connection between this reaction and suppurative processes in the body is based upon the following facts: (1) The reaction disappears in a few days after the incision of an abscess; (2) the reaction begins at the same time as does the disintegration of infiltrated tissue, *i. e.*, the formation of an abscess. The reaction does not appear if inflamed infiltrate undergoes resorption instead of suppuration. The iodine reaction affects almost exclusively the polynuclear neutrophiles, never appearing in the eosinophile. Notes were given of a case simulating typhoid fever. The iodine reaction gave the pus

reaction. Operation revealed an appendical abscess, which was evacuated.

Hydrencephaloecle.—Dr. Carl Beck of New York reported three cases of hydrencephalocele. In one the skiagraph showed the nasal bones separate from the frontal and pushed down. Two of the three are living after operation. The prognosis in hydrencephalocele is getting better under thorough asepsis.

Heart-Disease in Children.—Dr. Frederick A. Packard of Philadelphia read a paper upon "Antecedents of Valvular Heart-Disease in Children." The paper was based upon the analysis of the previous illnesses in 75 cases of endocarditis in childhood, with especial reference to the various infections. In 3 of the 75 cases no history of previous illness was obtainable. Of other diseases there was a history of rheumatism in 34 cases, chorea in 18, scarlet fever in 11, cerebrospinal fever in 2. His conclusions are that in many instances endocarditis must be attributed to such minor affections as coryza, skin affections, gastro-intestinal disturbances etc., instead of to the diseases more commonly supposed to be causes. A careful examination of the heart should be made after the occurrence of these diseases, as well as after the severer affections.

School Children.—The regular topic of the session, school children, was then taken up. Dr. E. Stuvey of Fort Collins, Col., presented a paper on "Symmetrical Development, or Does Our Present School System Develop the Highest Powers of the Child?" The physical, intellectual, and moral powers of the child should be developed at the same time. Teachers should have a more thorough training before beginning their work. They should understand the physiology of the brain and the development of the mind. There should be more enthusiasm in the work of teaching and less routine. Too many studies are given children at one time. More attention should be given to object-teaching, outdoor work in this line being of great value, mentally and physically. More time should be devoted to manual training. School sessions and recitations are generally too long and too many examinations are given. Whipping has been superseded by cruel and dangerous punishments.

School Break-Downs.—This was the subject presented by Dr. J. Henry Bartlett of Philadelphia. Reference was made to an article in a first-class monthly in which the writer claimed that 16,000 children in five large cities had been compelled to leave school in one term because of breaking down in health. The belief that this result, as claimed by the writer, is due to the present school system is unwarranted. Causes other than school-life which play a large part in ill-health, causing the child to leave school were considered. The principal ones are diet and haste in eating, lack of exercise, and the hours of sleep. These all occurring during the developmental period cause deterioration in the child's condition. Whatever the school strain may do, it has a host of allies. In some cases the school may be a safety-valve where the evil effects of some of the other influences may be set aside. A thorough study of the developmental processes needs to be made to get at the bottom of what the writer of the article in question calls a crime. The school system is good in many ways: too many examinations, etc., are simply an overdoing of a principle and are not essentially a condemnation of the principle itself.

Care of the Ear.—Dr. Louis J. Lautenbach of Philadelphia read a paper upon the "Care of the Ear in School Children." Statistics show that 7 per cent. of pupils have deficient hearing in both ears and from 13 to 25 per cent. in one ear. Young children are especially liable to ear-disease, because the Eustachian tube is open. An examination of the nose and throat is necessary when the ear is affected. A systematic examination of the hearing of all school children should be made. In this way the parents are helped and the physician gets to see the patient earlier and is more likely to be successful in treatment.

In the discussion on school children Dr. Wahrer said that the physician lacked the cooperation of the municipal authorities in dealing with this question. He has little sympathy with kindergartens in the way of getting children to work earlier. They are sent to school too early now and are taught too much in the beginning. He would abolish competitive examinations. Some children can do work easily and win prizes and first place without trouble. Others cannot and feel it a disgrace. Not every person can be a doctor, lawyer, or preacher. Educate children according to their capacity and ability to use knowledge. Every child should be examined by the family physician before it is sent to school.

Dr. E. E. Graham said that he doubted if developmental processes should be made the basis of the break-downs in school schildren. Developmental processes are natural and should not be blamed. Put the blame where it belongs—on the school. The system of fortnightly grading was condemned. The strain on medical students when examination comes but once yearly was cited and compared with these examinations of children every few weeks. The strain coming so often and on young children is productive of evil results.

Dr. Sutherland of Nebraska thinks the evils of our school system can be overcome, partially at least, by instituting two processes, *viz.*: (1) Make the qualifications of teachers greater. (2) Allow them more latitude in their function, by both the parents of their pupils and by the school board.

Dr. Allport of Chicago spoke regarding the system of examination of the eyes and ears of pupils which he has originated. This system is now working well in Chicago and is being adopted by other cities. He has never known a school board to refuse its adoption when it was intelligently presented. The tests are thoroughly unobjectionable to both pupil and parents. They are not obligatory. When a defect is discovered

the pupil need not go to any definite physician nor to any at all. The tests cost practically nothing, but $200 for Chicago with its 250,000 pupils. About 33 per cent. of children have defective eyes and 50 per cent. need treatment for eyes or ears.

Dr. Rosenthal stated that medical inspection in Philadelphia extended only to acute and contagious diseases. The family physician has great influence with parents and should not criticise medical inspectors, which has been done.

Dr. Lautenbach commended the German school system. He thinks good results will come from physicians working to have teachers given more power. He would not recommend having physical examinations under the control of school physicians, as they would be antagonized by the profession and by the public.

Liquid Air.—Dr. A. Campbell White of New York gave a demonstration of liquid air and spoke of the results of a year's use of this material in medicine at the Vanderbilt Clinic. A case for carrying the air was shown. In this it will last for several hours. It is now used as a spray and in a bulb as a cautery. It will not kill germs, but suspends their activity for a long time, they being brought back to normal only with great care. The question is whether this temporary suspension of vitality will not enable the body to completely destroy them. The effect of liquid air on human tissue is to cause a temporary local anemia followed by a great hyperemia If the cold has been sufficiently intense, a slough follows. Pain is not caused by its application, only a slight tingling being felt. Anesthesia lasts for some minutes. In an operation recently done for correcting a deformed hand a perfect result was obtained, primary union being secured. When the substance is applied over the spinal ends of nerves in neuralgia or herpes zoster, the pain is at once stopped. Small ulcers may result from this in old people of low vitality. Boils can be aborted by completely freezing and pricking in several places. It is the best form of treatment for carbuncle. Spray is introduced into the openings and then externally. A dry absorbent dressing is applied as very free bleeding follows. The good effect is thought to be due to the extreme hyperemia which follows. In the clinic it is used in place of the cautery almost exclusively. Liquid air greatly relieves the pain and odor of cancer and it is thought that early treatment may cure epithelioma. Experiments are now being made to determine the value of the vapor in the reduction of temperature. Results from the external uses mentioned have been very gratifying during the year it has been in use.

FOURTH DAY—JUNE 8TH.

Athrepsia Infantum.—Dr. Louis Fischer of New York read a paper upon "Athrepsia Infantum; Diagnosis and Treatment." Improper assimilation of food causes a lowering of the vitality of the child. The greatest number of cases occurs in bottle-fed children. Whenever a nursing child ceases to gain in weight, examination of the breast-milk should be made and cow's milk substituted, if necessary. The best form is not sterilized or Pasteurized milk, but good, clean raw milk. Aim at sterilizing cow and stable and utensils rather than the milk. Constipation is a great trouble in athrepsia and changing to cow's milk often stops this. The dried albumen of egg has given good satisfaction as an accessory food in these cases.

Intubation.—The Secretary read for Dr. Joseph Trumpp of Munich a paper upon "Intubation in Private Practice, and its Perfection." Statistics from 55 operators in Europe and America give 5470 intubations with a recovery rate of 35 per cent. before antitoxin was used and of 82 per cent. since its use. In Europe there is a decided opposition to the practice of intubation outside of hospitals. The writer argues for this, however. Previous practice should be made upon the cadaver or on animals. Explain to the parents the differences between the bloodless and bloody operations, meaning by the latter tracheotomy. As to the caliber of the tube, if there is no special indication for a smaller one, use that which will just pass. Rubber tubes are preferred instead of metal.

Injuries Due to Intubation.—Dr. Alexander Klein read for Dr. Janos Bokay of Budapest a paper upon this subject. Injuries are classified as follows: (1) Those which occur during intubation; (2) those caused by the presence of the tube; (3) those due to extubation. In 1200 cases only 4 resulted in formation of a false passage. Such cases are usually fatal. The sitting posture is advised for intubation.

In the discussion of these papers Dr. Welch of Philadelphia said that the safest place for intubated patients is the hospital. He prefers metal tubes, as they are not so liable to receive a deposit. He cited a case in which the tube was pushed down when removal was attempted. As the child was not suffering tracheotomy was not done and after a time the tube was coughed up. He is not so much in favor of antitoxin as are some physicians and thinks the statistics regarding it and intubation are not reliable and fair. All patients in the municipal hospitals receive antitoxin, but its results have not come up to his expectations. Their mortality in intubation cases is 58 per cent.

Dr. Rigg of Pittsburg finds that the best way to lessen the danger of intubation in private practice is to train a competent nurse in the use of the tube and to keep her in constant attendance upon the patient This makes the safety approach that of hospital cases. His results from intubation are not so satisfactory, as he finds that the membrane usually extends below the tube. The most important question in antitoxin treatment is that of its early use.

Dr. White of New York said that not so much reliance should be placed on statistics regarding

antitoxin, as epidemics might be mild or severe. Each physician can judge of its effect for himself by seeing cases in which it is not used and those in which it is employed. Cases are benefited by intubation even although the membrane extend below the tube, as the greatest difficulty in breathing comes from the upper part. The dyspnea from the membrane low down is more like that of pneumonia and not so urgent.

Dr. Fischer uses antitoxin as he would any drug of which he knows the effect. The first dose is 3000 units, repeated in twenty-four hours, if necessary. He advocates the use of rubber tubes and condemns the practice of forcible extraction by external pressure.

Dr. Rosenthal adheres to O'Dwyer's methods and tubes. In every case in which he used rubber tubes the child died. Italians always require two or three numbers higher than the scale would give. He advises large doses of strychnine in cases of prolonged intubation. In extubation do not try to find the tube. Pass the instrument along the finger and into the tube as if it could be seen and grasped exactly. This method will always succeed. Use no pressure, but withdraw instantly when the tube is entered. He always cuts off the silk and allows the child to lie as it pleases. Cases of croup in measles are very severe.

Dr. Welch said he had lately seen many cases of croup in measles and that they are very fatal. The question is whether it is diphtheritic. The Klebs-Loeffler bacillus is not always present. The croup is not necessarily due to the formation of an exudate, but in many cases seems to be caused by intense congestion of the mucous membrane.

Surgical Circumcision.—Dr. Ferd. C. Valentine of New York read this paper. Illustrations showing the technic were distributed. Anesthesia is generally needed. None but physicians should do the operation, as it is a surgical measure and surgical asepsis should be carried out. Religious liberty would not be interfered with by this rule and laws should be enacted to this effect. In answer to questions Dr. Valentine stated that fewer circumcised than uncircumcised men came for genito-urinary treatment. The question of advising the circumcision of every male child is a large one and he does not think it wise to advocate publicly this procedure. He would circumcise in every case when asked by parents to do so.

The following papers were read by title: "Treatment of Ear Complications in Measles, Diphtheria, and Scarlet Fever," by Dr. C. W. Hoopes of Philadelphia; "Rheumatism," by Dr. S. E. Woody of Louisville; "Chorea," by Dr. J. Clements of Kansas City, Mo.; "Medicinal and Surgical Treatment of So-Called Scrofula," by Dr. G. M. Blech of Chicago; "Essential Points of Difference in Treatment of Adolescent and Senile Heart," by Dr. John A. Robison of Chicago; "Abortive Treatment of Pneumonia," by Dr. H. Illoway of New York; "Eye-Strain," by Dr. T. H. Fenton of Philadelphia; "Neglect of Teeth in Children," by Dr. A. D. Rosenthal of New York; "Physician's Responsibility in Physical Education of School Children," by Dr. Grace E. Spiegle of Philadelphia; "Movable Kidney in Children," by Dr. I. A. Abt of Chicago; "Symptomatology of Appendicular Inflammation in Children," by Dr. T. H. Manley of New York; "Normal Salt Transfusion in New-Born for Hemorrhage from Cord," by Dr. J. S. Miller of Philadelphia; "Some Joint Diseases in Children: Their Diagnosis and Treatment," by Dr. E. A. Tracy of South Boston, Mass.; "Diseases of Antrum of Highmore in Young Children, with Report of Case," by Dr. Emil Mayer of New York.

The following officers were chosen for the ensuing year: Chairman, Dr. S. H. Kelly of Cleveland, O.; secretary, Dr. William E. Darnall of Atlantic City, N. J.

BOOKS RECEIVED.

The Medical News *acknowledges the receipt of the following new publications. Reviews of those possessing special interest for the readers of the* Medical News *will shortly appear.*

The Ophthalmic Patient. A Manual of Therapeutics and Nursing in Eye Disease. By Dr. Percy Fridenberg. Demi 8vo., 320 pages. Illustrated. The Macmillan Company, London and New York.

International Clinics. Edited by Dr. H. W. Cattell. Vol. I. Tenth Series, 1900. 8vo., 315 pages. Illustrated. J. B. Lippincott Company, Philadelphia.

The Annual of Eclectic Medicine and Surgery. Volume VIII. Edited by Dr. John V. Stevens. 8vo., 822 pages. Illustrated. Cincinnati, Ohio.

The Care of the Child in Health. By Dr. Nathan Oppenheim. Demi 8vo., 308 pages. The Macmillan Company, London and New York.

The Treatment of Fractures. By Dr. C. L. Scudder, assisted by Dr. F. J. Cotton. 8vo., 433 pages. Illustrated. W. B. Saunders, Philadelphia. $4.50.

Diseases of the Intestines. A Text-Book for Practitioners and Students of Medicine. By Dr. Max Einhorn. 8vo., 391 pages. Illustrated. William Wood & Company, New York.

The Cell in Development and Heredity. By Edmund B. Wilson, Ph.D. Second edition. Revised and enlarged. 8vo., 483 pages. Illustrated. The Macmillan Company, London and New York. $3.50.

Transactions of the New York State Medical Association. For the year 1899. Vol. XVI. Edited for the Association by M. C. O'Brien, M.D. 8vo., 887 pages. Published by the Association. New York.

A Practical Treatise on Sexual Disorders of the Male and Female. By Dr. Robert W. Taylor. Second Edition. 8vo., 438 pages. Illustrated. Lea Brothers & Co., New York and Philadelphia.

Traité de Médecine et de Thérapeutique. Par MM. P. Brouardel et A. Gilbert. Tome septième. Maladies du nez, du larynx, de la trachée, des bronches et des poumons. Par. MM. Cartaz, Castex, Barbier, H. Barth, P. Claisse, Mosny, L. Landouzy, H. Triboulet, Grancher, Balzer, Méry et Le Noir. 8vo., 931 pages. Illustrated. J. B. Baillière et Fils, Paris.

ORIGINAL ARTICLES.

A PROTEST AGAINST SOME OF THE EVILS IN THE PROFESSION OF MEDICINE.[1]

BY J. A. WITHERSPOON, M.D.,
OF NASHVILLE, TENN.

THE honor of delivering the annual address on general medicine, which you have seen proper to confer on me, is one which I fully appreciate, and I now take the first opportunity presented to express to the Association as a whole my grateful thanks for so distinguished an honor.

I also take the liberty of hoping that what I may say at this time will receive the hearty approbation of this large body of representative men. Nearly all of my predecessors have spoken of the wonderful progress and brilliant successes of the profession, and, indeed, they have been truly marvelous. The latter half of the last century has been one grand triumphal march to the present high plane of rational, scientific, preventive medicine, until to-day we are utilizing every element in Nature to solve the many problems of disease.

Chemistry, with its fixed laws of precision, is now receiving its proper recognition and clearing many hitherto unknown fields of empiricism and doubt. The modern laboratory, with its multiplied methods of investigation, has done much to lift the veil of ignorance and mysticism which has so long obscured the true etiologic factor in many diseases, and made preventive medicine the grandest achievement of the age. The modern methods of differential diagnosis, more accurate clinical observations, confirmed by pathologic investigation, have done much toward making medicine an exact science.

We are justly proud of these accomplishments, and when we think of the vast army of laborers in this noble work of humanity and the daily spreading of this wonderful store of information broadcast through the medium of modern journalism, making it possible for the most obscure country doctor to keep fully abreast of the times, and by this means to acquire more knowledge in one year than could have been attained in a life-time, a century ago, we have every cause for self-congratulation.

But it is not the object of this address to linger over these bright, golden fields, except to express my thanks and grateful appreciation to my brothers in the profession. I deem it the proper time and place to call attention to some of the most grievous fallacies and hurtful errors that have fallen into the ranks during the onward march, in some instances obstructing the path to true and honorable progress. I am well aware that it is not politic at these annual reunions to call to mind unpleasant things, but we have a high and noble calling, the untarnished honor of which has been placed in our keeping by our illustrious forefathers in medicine, the protection of which should be as a sacred trust; hence, I dare strike the alarm-bell and call to arms those who are resting in a security born of a sense of duty well done. The old guard have long stood at the helm and safely guided the grand ship of honorable medicine into a harbor of calm where the Code of Ethics offers immunity to quacking, pathies and commercialism. But, while we are taking a well-earned rest, dark clouds have arisen, and threatening waves are breaking over the old ship. Therefore, I may be pardoned if I do not follow in the footsteps of some of my predecessors in omitting the advances of the past year, my excuse being an honest conviction of the necessity and an earnest desire, without malice, to protect the profession from the hurtful tendencies of the times.

Dictation by Pharmacal Companies.

The first stupendous error, one which is so vast in its influence that it hangs like a withering blight over the individuality of every man in the profession, is the dictation of the innumerable pharmacal companies, the self-constituted advisers in the treatment of diseases about which they know nothing, to the entire profession. All honor to worthy and legitimate scientific pharmacy; we should welcome it as a child of medicine, but, as is often the case, the child, as soon as it is out from under the wing of the parent, has grown "bigger than the daddy" and not only tells him how to treat every disease to which flesh is heir, but is condescending enough to formulate his prescriptions with full directions on them, many times omitting the formulæ, but always kindly telling him in what diseases to use them. They are so solicitous that they flood your office with blatant literature full of bombastic claims and cure-alls, and I am sorry to say, too frequently with certificates or articles used by permission from physicians who call themselves reputable. Of course, none of these doctors are members of this body, or even inhabitants of the United States, but live in our new possessions, or some other country without the privilege of resting in the bright light of the Code of Ethics of this Association—a code writ-

[1] Oration on Medicine before the fifty-first annual meeting of the American Medical Association, held at Atlantic City, N. J., June 5-8, 1900.

ten by the fathers, broad and liberal enough for any true doctor to practise medicine under for a life-time, without a blush upon his cheek.

But that is not all; these drug-houses are so afraid that some one will die through your ignorance or before dull comprehension becomes alive to the merits of their preparations, that they send a man, frequently a doctor who was a howling success in the profession before his health failed, to tell you all about how to treat disease. He leaves you with the parting injunction to always specify his preparations, and with the friendly warning to watch the local druggist—whom you know all about—to keep him from substituting, while he assures you that he and his firm—about whom you know nothing—are the personification of honesty, and that you can always depend upon them and their preparations, as the plants from which they are compounded were gathered by their special agent from the grave of Esculapius. And thus they come, with samples galore, until you are reminded of the old southern negro song, "They are coming, Father Abraham, forty thousand strong," to spread the glad tidings of joy, and make every doctor their walking advertising agent. They are the only people in the world who, without seeing the patient, can tell you how to feed the baby, until he blossoms like the rose, or how to restore the rose-tinted bloom of health to the blanched cheek of the convalescent. They have an antiseptic that can chase the bacilli typhosi through the lymph-channels and pound them to death in the blood-vessels by throwing red blood-corpuscles at them, or the white blood-corpuscles are called up as a reserve, and the war of the roses is again enacted in the human body. Or, they make the emaciated consumptive so fat that he can hibernate and convert his distressing cough into a laugh of joy. Thus, I might enumerate indefinitely what great things they are doing for us, but seriously speaking, gentlemen, this is a curse to the profession, and takes from it its real scientific application, *viz.*, treating each case upon its merit.

In my humble judgment, the fostering of these establishments is a disgrace to honorable medicine. The true sphere of pharmacy is to make the official preparations of drugs and compound our prescriptions. When a doctor acknowledges his inability to formulate his own prescriptions to suit each case, then he should seek some other occupation, more to his taste of commercialism, or less trying by reason of his lack of qualification.

These institutions have such powerful influence, that every medical society meeting must furnish space for their wares, this frequently becoming a place of popular resort where various drinks are served, this taking from the meetings the interest in their scientific work. Yet they are not satisfied with this; it is reported that they have even gone so far as to insinuate themselves into the very body of some of the sections, and that at this meeting they propose to dictate and control the election of officials who are kindly disposed to the manufactured products of their laboratories. Can this be true? Can we rest under such an imputation and retain our self-respect? If these reports be true—and the journals are agitating them, and I have in my possession a letter from a drug house to a journal, making the charge—then, indeed, has the reputation of regular medicine descended to a lower level than I thought. We must have an investigation, and if these charges are true, the time has come for vigorous action. If there are those who are making our holy temple a house of merchandise, then we should drive them from our midst by the scourge of our indignation and contempt as did Christ the money-changers of Jerusalem.

Multiplication of Medical Colleges.

Next, I desire to call your attention to the rapid multiplication of medical colleges in this country. In doing this I do not wish to ignore the great work that has been done by the profession through the development and progress of medical education. The notable advances of the past twenty years, such as lengthening the course of study, laboratory work, etc., have been inspired by the profession, and we have greater reasons to be proud, when we remember that these improvements have been carried out without assistance of large endowments, for very few even of our best institutions have had such aid. But, while we give credit, we must also lay to the charge of the profession the increase in poorly-equipped institutions that have been born of no need, and that are fostered to no good end. This evil has become especially marked in our great cities. It has become a fad and a means of advertising to organize a poorly-equipped medical college, both in teachers and modern means of instruction. The result is cheap notoriety, half prepared students, cheap rates and cheap doctors who bring discredit upon the profession and death to innocent people and who, as a last resort, go into politics and help enact laws harmful to the high standard of honorable medicine.

This induces young, inexperienced graduates to go immediately into a specialty, without experience or special fitness, which is never justifiable. No man is prepared to go into any special field until he has done general work to familiarize himself with disease in all of its phases, and neglect of this training is responsible for so many extremists who never temper their thirst for notoriety with common sense. It is this which has caused the loss of many lives and much unnecessary mutilation of the human body. It is this that gives birth to fads and faddists. It is more than probable that the appendix of our forefathers occupied a position downward from its cecal attachment until the surgical dictum went forth, "No man is a perfect man, so long as he has his appendix." Now you find this trouble-

some little remains of the "missing link" has left its normal habitat and hidden behind the cecal pouch.

Again, take the spectacle fad. Glasses in the past were an insignia of honorable old age; now we truly find them from the cradle to the grave. Even the negro "coon," who has been noted for keenness of vision, following the uncertain meanderings of the opossum with unerring precision during the dark of the moon, or seeing a chicken on the highest roost the darkest night, must now have "specs" to walk the streets in broad daylight.

All honor to true and legitimate specialism; it should be welcome and aided by every general practitioner, as a scientific and correct division of labor in a field broad enough for all, but this rushing into specialism without the above preparation is truly appalling, and, in my opinion, is injurious, not only to the general profession, but to the truly well-equipped specialist.

Laboratory Diagnosis.

I desire to call attention to another serious error which seems to be the popular tendency of the times. I refer to laboratory diagnosis regardless of clinical symptoms. The microscopic demonstration of the presence of etiologic germs of a disease is not sufficient for diagnosis, but only confirmatory; the clinical manifestations should be present, and the close and careful observer at the bedside must remain the highest court, and chemical and microscopic tests his aids. I believe in adhering to bedside experience. The considering of the case in all its details—history, tendencies, vitality, general aspect, physical signs, subjective and objective symptoms—aided by the microscope and modern methods of research, when needed, is the only way to practise medicine with justice to yourself and safety to the patient. It is an unfortunate fact that many laboratory men know the habits, morphology and methods of culture and staining of pathologic bacteria far better than they understand by experience or observation the diseases these bacteria produce. We must not lose sight of the fact that, while it is right and gratifying that this work is being done and is of great value to medicine, our true mission is to save human life.

Medical Politics.

Here let me express my earnest condemnation of medical politics. I am old fogy enough to believe that we should confer honors upon those to whom honor is due, and method of wire-pulling, or resorting to the tricks of ward politicians, is unbecoming and should not exist in a medical society, especially in this, the largest and most influential medical society in the country. It can only bring discredit to its members and cripple its usefulness. Here, the queen of professional ethics should reign supreme, and, by the light of example, shed her beneficent luster upon the world. The man of true merit, to whom his professional brethren would naturally turn when honors are to be conferred, is often overlooked because his modesty prevents him from advancing his own interests, while men of less ability, but with more "pull," are placed in positions of honor. This should not be.

One of the most grievous and dangerous errors is the present system of quarantine against epidemic diseases. I refer to local boards of health acting independently, often composed of most inefficient men who owe their position to political preferment rather than to any special fitness for the place. State boards acting independently of other boards are largely responsible for the shotgun quarantine, useless disturbance of business and often ineffectual attempts at protection.

If there is any one department of medicine which stands preeminently in the front rank of advancement in this progressive age it is preventive medicine, and, with our increased knowledge, it is a reflection that any serious epidemic disease should gain a foothold on American soil. The only way to prevent this is by giving the power to a National Board of Health. Away with the old political cry of State rights when the lives of our people are threatened. Let us place the strong arm of this Government around this land, unhampered by petty jealousy and minor boards. We are confronted by a serious and grave question involving this very principle. Even now, at the Golden Gate, which has always stood wide open to welcome the stranger, that fearful scourge, bubonic plague, has insidiously gained admission. This Association has time and again, directly and indirectly, expressed its views upon this subject, and appealed to the nation through its representatives, but as yet the full measure has not been meted out. When war with Spain was declared, millions of good "coin of the realm" was voted, and a million men stood ready to enlist and fight for the flag of the grandest country on earth. And yet, a disease is threatening us now, which has claimed more victims than the combined armies of the world, and finds us unprepared to meet it properly. We must make united efforts in the establishment of a National Board of Health, clothed with legal power and supplied with the necessary funds, to protect our people from these threatened invasions of the pestilence that stalketh by night and wasteth by noonday, peering with his grim face and shaking his matted locks, while from his parched lips he emits the gibberish of a foreign tongue. When armies and strong men falter, and tardy statesmen sit with faces pallid by fear and guilty conscience, then the world will turn to us, as the protectors of human life, to buckle on our armor and advance to meet the foe, and we must be prepared to do as our profession has always done—advance with a cool head, a brave heart, and unselfish love for our fellow-man.

If by united effort we can get Congress to see that no department, not even the Treasury, is more important than the health of our people, and if we can have our Chief Executive appoint the man for the position, allowing the same assistants and clerks as that of any other of the departments, then we shall be able to stop the invasion of foreign disease, and surely every patriotic citizen can trust the President, regardless of politics, under proper laws enacted by our representatives, to solve this weighty problem.

Indiscriminate Use of Narcotics.

We should at this time sound a note of warning upon the growing tendency on the part of many physicians to use morphine and cocaine indiscriminately. There are but few men here of wide experience who do not daily come in contact with practitioners whose panacea for everything is opium in some of its forms, and while I regard it as a wonderful remedy, capable of great good when judiciously used, I am bound to say that when used as it is by some doctors, it is productive of terrible results. The morphine habit is growing at an alarming rate, and we can not shift the responsibility, but must acknowledge that we are culpable in too often giving this seductive siren until the will-power is gone, and a moral and physical wreck is sent down to shame and degradation, often committing crimes while in the toils of his perverted nature. Nor do the fearful results stop here; too often these tendencies are transmitted to the offspring and these innocent victims are brought into the world, half-made mentally, morally and physically, thoroughly unfitted for the many emergencies of life. Ah, brothers! We, the representatives of the grandest and noblest profession in the world, with the God-given mission of making growth more perfect, life more certain and death more remote, must shoulder the responsibility, follow in the footsteps of the Great First Physician, and warn and save our people from the clutches of this hydra-headed monster which stalks abroad throughout the civilized world, wrecking lives and happy homes, filling our jails and lunatic asylums, and taking from these unfortunates the precious promises of eternal life. The hypodermic "shot," as it is affectionately called, is too often given in a stomach-ache, when a dose of oil is needed, or to relieve painful menstruation month after month, until the bright, rosy-tinted cheek of health and the brilliant eye of youth and healthy young womanhood give way to the dry, pigmented skin and the leaden expressionless eyes of the morphine habitué, and a life full of promise and usefulness is blighted forever. Why not seek and remove the cause of these, as well as many other ills for which morphine is given, and thus avoid the specter which, if you are a conscientious physician, will follow you through life and like Banquo's ghost will not down? The same can be said of cocaine, which is rapidly becoming a national evil, because of its indiscriminate use in minor surgical operations, and of the unnecessary and hurtful information too often given the laity of its seductive influence on human beings.

Useless Multiplication of Books.

In approaching the next subject, I feel, before this body, like following the example of the great lawgiver and taking off my shoes, for I realize I am on holy ground. But remembering the maxim of one of the pioneer heroes of my native State, "Be sure you are right, and then go ahead," I have determined to offer my feeble protest against the useless multiplication of books and authors. Every progressive man in the profession feels the necessity of keeping fully abreast of the times, and when a new book is published, will purchase it for fear he may lose some valuable information, too often, to find many of them poor copies of other works, without an original thought, or any necessity or reason for their existence, except, perhaps, the ambition of the author. Every medical library, public or private, is groaning under its load of useless repetition, in systems of many volumes. There is a prevailing tendency amounting almost to mania in young men, to rush into print, and I feel that I can talk freely to them, being one myself. This is especially true in our great cities, for, how often do we see a young graduate, after staying in a hospital a year, and then in a laboratory a short time, suddenly unfurl his banner to the world as an authority, and while his English is excellent and his diction perfect, I doubt whether his experience warrants him in assuming the grave responsibilities of an authority on any subject where human life is at stake. I would not be understood to mean that the young men should remain in the rear and withhold any information they may have acquired by arduous labor, nor would I check their worthy ambition or pluck one laurel from their brow, but I do claim their medium should be the medical journals, which are, after all, the greatest educators of the busy physician. When such a man as Osler, a walking encyclopedia of medicine, regrets the day when he sold his brain to the medical publisher, it is time for younger men to pause and consider before they assume the rôle of authorship.

In conclusion I desire to say that a conscientious sense of duty alone induces me to call attention to the threatening storms which, if not checked while they are yet young and harmless, will eventually undermine the very foundations of true and honorable medicine. Mr. President, when all of these injurious things have been forever eliminated, and the regal robes of ethical medicine rendered aseptic from their present pollution, then we can exclaim with pride, "Sound the loud timbrel o'er Egypt's dark sea, Jehovah hath triumphed; His people are free."

SOME OF THE PHYSIOLOGICAL METHODS AND MEANS EMPLOYED BY THE ANIMAL ORGANISM IN ITS CONTINUAL STRUGGLE AGAINST BACTERIA FOR MAINTENANCE OF LIFE AND HEALTH.[1]

BY S. J. MELTZER, M.D.,
OF NEW YORK.

THE author states at the outset that bacteriological literature contains a number of important facts which can be brought together and organized into an answer to the problem presented by the title of this paper. But it must be acknowledged that those facts were not discovered to find the cause of health. Bacteriology was born and raised chiefly as a part of pathology, and it did not concern itself so much with the normal course of life, as with its exceptions and abnormities. It was attracted by the problems of immunity and of recovery from infectious diseases.

There is still another feature in bacteriology which, to my mind, is inimical to the proper treatment of the problems of the defenses employed in normal life and which deserves some special discussion. It is the tendency, prevailing in bacteriology, to anticipate only a single factor which does the fighting in the battles of the body. Thus, we see one large group of investigators believing exclusively in the theory of phagocytosis, while another group swears only by the alexines. It is interesting to note that the line of division between the two groups is the same here as it is in pathology. The old school of pathologists believed that the cause of all diseases was located in the body-fluids, or in the blood—humoral pathology; the new school looks to the cells of the body as the seat of the evil—cellular pathology. The enemy resides either in the blood or in the cells, and so is the defense to be found either in the blood or in the cells. The schools differ as to the character of the leaders, whether admirals or generals, but they agree that the attack, as well as the defense, can be carried on only by a single leader.

When some sixty years ago the young school of physiologists of those days had demolished the idol of vital force, they rendered a great service to the science of biology by opening up all mysterious paths and phenomena of animal life to the searching light of the modern investigator, who learned to work with methods employed in the exact sciences. This service was and is generally appreciated; it consisted in the abolishment of the idea of vitalism. But the scientific revolutionists of those days have rendered to physiology another important service which, as far as I can see, has never yet been clearly pointed out. When they overthrew the irresponsible reign of the vital force, they did not attempt to replace it by another single-headed force—they simply converted the monarchy into a republic! Within the last half century the domain of physiology was toiled by an army of painstaking workers, throwing their search-light into every corner and crevice of animal life; but until very recently no attempt was made to single out a tissue, a system, or a process as the leading spirit of the living mechanism. Neither the nervous nor the circulatory systems, neither the anabolic nor the catabolic processes, and neither the blood nor the cells were singled out to be entrusted with the leadership of the whole. The constant reappearance of the same morphological unit—the cell—in the histological studies of the tissues of the body, naturally did not impress the minds of the physiologists, whose object of study was chiefly the function, and not the form. But even the frequent reappearance in many body-tissues of one and the same functional phenomenon—the irritability—did not mislead the student of physiology to proclaim this characteristic feature of living tissue as the *primum mobile* of the life-machinery. The shape and quality of the bricks used in the erection of a building do not decide its nature and destination, whether it be a mansion, a monument, a factory, etc. Moreover, the animal body consists chiefly of a great number of harmoniously working mechanisms, in each of which all tissues, systems, etc., are participating in its complex construction, and it is still a great and open question, whether any tissue takes part in the work of the body directly, without the intervention of a mechanism. But here again no exclusive leadership is entrusted to any special mechanism. To be sure, the propeller of the circulation is an important mechanism, a serious impairment of its working is sure death. But neither should the modest gateman at the entrance of the larynx be underrated; failure of the prompt closure of the glottis during each deglutition, would cause suffocation and death. The same applies to the standing of the participating tissues within each mechanism. The respiration, for instance, is affected not only by such important changes as occur in the metabolic processes, in the composition of the blood, in the nerve-cells within the respiratory center, etc., but also by changes in tissues of apparently such low vitality as are the elastic fibers of the lungs or the cartilages of the ribs.

In short, the unity of life is an ideal commonwealth, without a king or an almighty president. It is governed by all its citizens, working in committees, each one of which performs its task, high or low, with promptness and exactness, to accomplish in the first place its own end, but also with an avowed purpose to be in steady communication and co-operation with all the other committees; thus securing a harmonious, concerted action of one and all—for the welfare of life and health.

It is not here the place to speak at still greater length of the correctness of such a view within the domain of physiology. Nor shall I discuss here the applicability of a similar view to pathology. But I shall insist upon that the prevailing view in bacteriology with regard to the defense

[1] Author's abstract of paper read by title at the General Session of the Congress of American Physicians and Surgeons, May 1, 1900.

of the body against bacteria, *viz.*, that it is entrusted chiefly to a single element (be it the blood with its alexines, or be they the leucocytes, or the other body-cells), is neither correct nor advantageous. It is incorrect, because it is improbable that the republic government of the body, in which all parts are working harmoniously in all the other struggles of life, should delegate the steady struggle against bacteria to a single tissue. On the contrary, it seems rather highly probable that, like in all defenses, every tissue, system, and mechanism is called into service to combat the invasion at every step and by any attainable means. And it is disadvantageous, because experimentors who concern themselves with finding exclusive principles which are capable of destroying bacteria and their products in experimental diseases to a value of 80 or even 100 per cent., have only contempt for factors in the struggle which could contribute to the successful end only 4 or 5 per cent., which is often below the possible experimental error. While in the natural struggle of life the army of the invading bacteria are met by a small army of trained defenders, each one of which, may be, contributes to the success indeed only one per cent. or even only a small fraction thereof, the sum total of all of which represents nevertheless a hundred per cent.!

Backed by the preceding considerations, I venture to offer the following two suggestions of a general character:

I maintain in the first place that in the struggle against bacteria the defense of the body is not carried on, exclusively or chiefly, by a single element. It is neither the body-fluids, nor the leucocytes, nor the other body-cells alone which can claim the exclusive merit of maintaining the health of the body, but each and everyone of them has its variable share in attaining the desired end.

I maintain furthermore that in health, at least, the actual defense is carried on not by a single tissue, or a single function, but by concerted action of several tissues and functions, by the working of a mechanism. By mechanism I mean the co-operation of several independent factors in attaining a common purpose. Let us take as an illustration the protection of the conjunctival sac. It is nearly in direct contact with the air, and we might expect to find there an extensive bacterial settlement. Nevertheless Lachowitz and Bojwid found that in 69 per cent. of cases the conjunctiva was perfectly sterile. The factors which accomplish this sterility, or at least the comparative sterility of bacteria, are: The reflex which causes the closure of the lids at the approach of dust (the carrier of bacteria); the blinking which occurs regularly a few times in a minute and which, in conjunction with the lacrimal moisture, throws out again mechanically the already-landed bacteria; and, finally, the bactericidal effect of the tears destroys the balance of the invaders. Or let us take the respiratory organ from the larynx down to the respiratory tissue, including the corresponding lymph-glands. I would like to call attention to the unique position of the respiratory path, which perhaps has never yet been sufficiently pointed out. Through this path the outside world stands in an intimate relation with the interior of the body, inasmuch as the air-column is separated from the lymphatics and capillaries of the lungs merely by a single layer of the very thin epithelium of the air-cells. Even the serous cavities are separated from the lymph-spaces by thicker layers. This arrangement is, of course, indispensable for the proper exchange of the blood-gases with the air. But what prevents the bacterial invasion of the interior of the body by this open and direct way? Morcover, most of the writers agree that trachea, bronchi and lung tissue of healthy animals are nearly sterile. In a number of rabbits under morphine anesthesia I found all these parts to be sterile. If one vagus, or a laryngeal branch, was cut, then the upper part of the trachea contained bacteria, but not the lungs. When both vagi were cut, then of course the lungs, too, were invaded. Jundell reported recently that by means of a special device he was able to test the human trachea, and found that in the majority of healthy cases the region below the glottis proved to be sterile. What protects this path? In my opinion the result is accomplished by the co-operation of the following factors:

The tortuose part of the respiratory path lying above the glottis removes, perhaps, the greatest part of the bacteria contained in the inspired air-column and the remaining number is, under normal conditions, just small enough to be disposed of by the factors present below the larynx. Bacteria which pass the glottis are either carried back outside of the glottis from the trachea and the bronchi by the steady movements of the cilia of the epithelium; or, if the germs are carried in the center of the air-column down to the air-cells, they quickly penetrate the thin epithelial layer and are immediately within the reach of the lymphatic glands which take good care of them. The ready penetrability of the air-cells I consider a favorable factor, because, if the bacteria were retained for some time in the alveoli, they might settle there, proliferate, form a necrotic focus, and overflow the body with toxins, or even with bacteria, entering directly into the capillaries. As to the activity of the lymph-glands, the observations of Loomis, Pizzini and others are very instructive. The lymph-glands of more than forty per cent. of non-tuberculous lungs contained living bacilli. The reduction of the invading bacteria to a small number is essential for the success. In inhalation experiments with large numbers of bacteria thrown into the respiratory path, the normal mechanism fails.

In this illustration we see how an entrance which is most conveniently open to the invading bacteria is guarded successfully, not by a single tissue or function, but by a combination of more or less valuable factors—by a mechanism.

In connection with the respiratory path, I would like to recall here the interesting fact that

both canals which lead furthest to the innermost of the body, that is, the respiratory and the female genital canal (which latter terminates in the peritoneum) have ciliated epithelium, the movement of the cilia being outward and are, as far as the epithelium extends, entirely or nearly sterile. The tendency of our times is to underrate the value of mechanical factors. What energy those movements of the cilia represent has been shown by our distinguished president some twenty-five years ago. According to his calculations the work accomplished by one cilia within one minute would be sufficient to lift its own weight 4000 meters.

Turning to the plan of defense throughout the entire body, I have to state at the outset that in its outlines it is much the same as seen in the two mechanisms already cited. Thus the aim is to greatly reduce the number of bacteria by mechanical methods and then to destroy the remnant by some biological means. The mechanical methods are: Barricading the entrance, throwing out again the landed bacteria, or carrying them to the place of destruction. The following is a short sketch of the physiological defense-work, carried on throughout the entire body.

The bacteria are decimated at their entrance into, and their advance within, the body cavities. They encounter in the mucous membrane the first and in the net of lymph-glands the second barrier against their invasion of the interior of the body; and, when finally there, a part of them is thrown out again with the bile, the urine, and the sweat.

The number of bacteria remaining within the interior of the body is in normal conditions comparatively small, and these are readily destroyed by the factors entrusted with this task. What are these factors? We know that when saprophytic or moderately virulent bacteria are introduced intravenously into a healthy animal body, they disappear not only from the blood, but also from the entire interior of the body within a comparatively short time. Bacteria grow well on proteid-media, and develop rapidly in dead bodies. They settle and develop well even in living bodies, if they find there necrotic foci, as was shown among others by the experiments of Cheesman and myself. But diminish the vitality somewhat, as by chronic heart and kidney-diseases, and the invasion and settlement of micro-organisms in the body is encouraged, as was well demonstrated by Flexner in his paper on terminal infections. It is thus an established fact that the healthy living body destroys the invading bacteria. By what means? Metschnikoff and his followers believe that it is done chiefly by the leucocytes. We cannot discuss here the immense material brought forward for and against this theory. The impartial opinions seem to have settled upon the conclusion that the leucocytes undoubtedly often assist in the work of the destruction of the bacteria. They are, however, neither the exclusive, nor even the chief actors in this work. Buchner, Denys, and many followers, believe that the destruction of the bacteria within the body is accomplished by the bactericidal elements which are surely present in the blood outside of the body. The proof, however, is still lacking that such exist and are effective in the circulating blood within the animal. It is, however, gratifying to observe, how the differences between these two leading theories have gradually dwindled. The present status is as follows. Metschnikoff now admits that the body-fluids also contain some bactericides, but he maintains that they are derived from broken-down leucocytes; and Buchner now takes the ground that the alexines are derived from the living leucocytes which secret them. The mechanism phagocytosis consists in the positive chemiotaxis which causes the attraction; in the wandering of the cell to the micro-organism; in the embracing or catching of it, dead or alive, and in the chemical digestion of the germ within the cell. In Buchner's theory the cells are attracted by and wander to the bacteria, in the neighborhood of which they secret the deadly alexines.

(The author here gives a brief account of the discoveries made in the studies of the phenomenon of immunity; for instance, the several kinds of antitoxins, the antimicrobic sera, the lysius and the agglutinins, the instructive and widely-accepted theories of Ehrlich, the bacteriolytic enzymes of Emmerich and Loew, etc.)

The facts and theories briefly referred to are very far reaching and of primary importance. But for the present they cannot yet be utilized satisfactorily for the explanation of the rapid disappearance of numerous bacteria from the interior of the normal animal body.

I might be permitted to state here briefly the suggestion of two new factors, which, in my estimation, are capable of assisting in the work of the destruction of bacteria within the body.

One of these factors is the process of plasmolysis. When cells having membranes are placed in a salt solution, more concentrated than that to which they were accustomed by the osmotic interchange of salt and water, the latter leaves the cells and the protoplasm recedes from the membrane. The same is true also of bacteria. When the vacuolization takes place at the long sides of a bacillus, the vacuoles may meet at the middle of the long axis and the receding protoplasm appears divided in two parts, presenting sometimes the appearance of a diplococcus surrounded by a halo. If the solution is soon diluted again, the cells may regain their normal appearance, although sometimes the membrane bursts when the change is too sudden. When the injurious concentration continues, the changed form might become permanent, or at least will yield very slowly to a later dilution. Even in the permanent change the cell will continue sometimes to live, but offers then but little resistance to any accidental injury. Now even in the same class of animals the body-fluids of different species, or even subspecies, have a different osmotic pressure and what is isotonic for this species might be hypo-

tonic for one and hypertonic for another species. As there is no proof, nor even any good reason, for the assumption that the blood and the other fluids of the animal body are isotonic with the protoplasm of the bacterial cell, may we not assume that the fluids are hypertonic, and therefore plasmolytic for bacteria which get into them? And as the organisms remain in the hypertonic animal fluid for some time, the state of plasmolysis becomes permanent and the bacteria succumb easily, either to the effects of the plasmolysis itself or to some insignificant accidental injury?

Baumgarten, who for years opposed the theory that the bactericidal properties which are manifestly present in the extravascular blood exist and are active in the circulating blood, recently came out quite strongly for the assumption that the destruction of bacteria in the extravascular blood is chiefly due to plasmolysis. It is surprising that he does not even discuss the question whether also the blood within the living body might be plasmolytic for the invading bacteria. Here he repeats his often-pronounced opinion that the natural immunity rests chiefly on the absence of certain nutritive elements within the living organism which makes the latter an unsuitable medium for certain bacteria. I am not aware that the suggestion I make was ever brought forward before. But I am going to enlist in favor of my hypothesis certain important observations made by a distinguished member of our Congress. I am doing it with great reluctance, as I am afraid that my interpretation of the facts will not receive the sanction of their discoverer. In a series of communications Professor Adami has reported a number of extremely interesting facts concerning the presence of diplococcoid forms of bacteria in the liver, kidneys, etc., of which I shall mention here only the following: When a culture of the colon bacillus is introduced into the ear-vein of a rabbit, there appear after some short time in the liver and the kidney bacterial bodies resembling diplococci which are surrounded by a halo. Such bodies are also found in the liver of normal adult rabbits, but not in the livers of very young ones. Similar bacterial bodies develop also in body-fluids when inoculated outside of the body with the colon bacillus. That these bodies are actually remnants of the colon bacilli is proven by the fact that some of them gradually assume normal forms when reinoculated in suitable media. Now, double dots surrounded by a halo is just one of the forms into which bacteria are transfigured by plasmolysis. I therefore risk the interpretation that Professor Adami has practically discovered the degeneration of the invading bacteria by plasmolysis, for which I put forward the claim that it is one of the regular factors in the defense of the body against bacteria.

The second new factor, which I believe has a regular place in the lines of the defense, is the vibrating effect of the heart-impulse. By the analysis of many data existing in the literature regarding the significance of vibration to cell-life, and on the basis of results of my own experiments, I arrived at the conclusion that the relations of vibration to life are similar to those of temperature. A certain minimum is indispensable to all forms of life, a certain maximum cannot be overstepped by any one, and there is a certain optimum for every one. But every species of cells has its individual minimum, optimum and maximum. I found that a certain degree of vibration which was an optimum for one kind of bacteria was destructive for another kind. In recent experiments, a repetition of experiments made by Professor Welch and myself some years ago, I could establish the validity of this law also for the red blood-cells. In a previous paper I made the remark that the vibrations emanating from the impulse of the heart form probably the optimum for the living cells of each individual animal. Now, recent experiments have shown me that the vibrations communicated to the body by the heart are deleterious to extravascular, dead blood. I have placed small rubber-bags or bottles with blood in the peritoneal cavity, or in the subcutaneous tissue of animals, and found that the red cells of this blood were destroyed much earlier than those of the blood which was kept in thermostat at a temperature equal to that of the inside of the animal. The suggestion which I wish to make is that the vibrations emanating from the heart-beat of the animal is more than a maximum for all the bacteria invading the interior of the animal body, especially in the injured state into which they are placed by the other influences of the body, for instance by plasmolysis.

From the observations of Adami and other investigators, we might consider it as an established fact that the interior of the adult body is regularly invaded by a number of bacteria, which, however, do not settle there, but are sooner or later destroyed. What effect does this constant invasion and destruction have on the body? If we introduce bacteria by some artificial method into the interior of an animal, we immunize this animal. Why should it be different when the bacteria invade the body by natural ways? I believe, therefore, that the regular, moderate invasion of bacteria into the interior of the body is far from being an infection, an evil; it is a means of immunization, at least against the evils of an invasion of the same kind of bacteria in numbers larger than usual. The immunization is, of course, not strong enough to show the presence of antimicrobic serum within the blood; neither is it equal to meet the emergencies of extraordinary invasions. But we do not know whether it is not due partly to this perpetual immunization that disease is such a rare exception.

Latent infection, therefore, is not a foe to normal life, to health, but is rather a confederate in the defense of it.

Appointment at Charity Hospital.—Dr. E. M. Foote has been appointed visiting surgeon to fill the vacancy caused by the resignation of Dr. J. B. Walker.

SOME POINTS IN THE MANAGEMENT OF OBSTETRIC CASES IN PRIVATE PRACTICE.[1]

BY JOSEPH BROWN COOKE, M.D.,
OF NEW YORK.

IT is not my intention to go over the entire ground of the management of obstetric cases in private practice, but merely to mention, in a more or less disconnected way, two or three points in technic, the importance of which has not, so far as I know, been sufficiently emphasized.

Few physicians in general practice make any effort to systematically record and preserve for reference histories of all their cases, and the adoption of such a system, especially in obstetric practice, cannot be too strongly urged.

A pregnant woman may be well compared to a ship at sea. The chances are that she will arrive in port without accident or mishap, but, unless a most vigilant and unremitting watch is maintained from the beginning to the end of her voyage, disaster may overtake her at any moment. In like manner serious and unlooked for complications may arise during the course of pregnancy unless every precaution against their onset is observed.

To guard against this danger and to avoid the possibility of overlooking the presence of any unfavorable symptom, however slight, an accurate history of every case must be kept from the time when the patient is first seen until the end of the puerperium. In addition to the benefits that accrue to the patient by the adoption of such a system, the physician is placed in a position to profit by his own experience in the fullest sense of the phrase and every case will serve as a stimulus to better work and clearer judgment. History-books are only suitable for hospital use and are comparatively valueless to the practising physician. He comes in contact with his patients under a great variety of circumstances, often when he least expects them, and his records, to be of value, must be made on the spot and not written down from memory after a lapse of many hours and often of several days. Consequently he must provide himself with some means of recording every important feature of his cases at the moment when the information is imparted to him, and this indication is filled in an ideal manner by the use of history-cards which can be carried in the pocket as long as the patient is under frequent observation and afterward put on file for reference.

My own cards, for assistance in the preparation of which I am greatly indebted to Dr. J. R. Tillinghast, do not differ essentially from others that I have seen except that they are considerably smaller and can be carried in the pocket without folding or bending.

Three cards are used for each patient; one for the pregnancy, one for the labor and one for the puerperium. The pregnancy-card has space on its face for the patient's name, address, age, nationality, date of marriage and date of expected confinement. Below this are recorded her family history, personal history, especially as regards rickets, scarlatina, diphtheria, nephritis and syphilis, the physical examination of her heart, lungs, liver and spleen, and her menstrual history, with the age at which menstruation began, the interval between the periods, the duration and amount of the flow, and the presence or absence of pain before, during or after the flow. If the woman has been pregnant before a brief history of her previous pregnancies, previous labors and previous childbeds, is recorded in the space provided for it, after which the date, duration and amount of her last menstruation are noted.

Her present pregnancy is next investigated and space is provided for notes on vomiting, headache, edema, arterial tension, albuminuria, and any treatment instituted. If quickening has occurred the date on which active fetal movements were first noticed is recorded. The back of the pregnancy-card is devoted to the examination of the patient, which is made not later than the thirty-second week of gestation and usually at a somewhat earlier period. This examination covers the condition of the breasts, abdomen, uterus, pelvis, fetus, vagina, cervix and perineum, and nearly half the card is left blank for any other matters that may suggest themselves in individual cases.

The labor-card bears on its face a minute record of a normal labor, together with notes on the placenta, membranes, cord, hemorrhage, perineum, cervix, infant, douches if any, and the maternal condition for one hour postpartum. On its back are spaces for recording a forceps operation, a version and a breech delivery, with half the card blank for remarks. The puerperium-card covers two weeks and has space for daily notes on the condition of the mother's breasts, fundus, lochia and bladder, and the infant's eyes, cord, bowels, urine and weight. Below this is recorded the examination of the mother's breasts, uterus, cervix, perineum, adnexa and general condition at the end of the puerperium and of the infant's eyes, navel, buttocks, genitals, nursing and general condition. On the back of the puerperium-card is a two-weeks' temperature chart ranging from 97° to 105° F., and space for daily records of the woman's pulse, respiration, urine and stools.

At the termination of the case the three cards belonging to it are placed in the filing cabinet for future reference. A leather pocket-case is supplied with the cards, in which twelve or fifteen may be carried comfortably. Two or three blank pregnancy-cards should be kept with the others so that the history of a new patient may be begun when she is first seen, whether it be at the physician's office or in her own home. Beyond the matters suggested by the headings on the history-cards, there is little to be said as to the management of pregnancy except on the subject of urinary examinations. The urine should be examined within a week of the patient's first visit and

[1] Read before the Section on Obstetrics and Gynecology of the New York Academy of Medicine, March 22, 1900.

then monthly until the end of the seventh month of gestation, after which analyses should be made weekly, or oftener if necessary, until labor has taken place.

For a long time I found the greatest difficulty in securing specimens for examination with any degree of regularity. Often the patients would forget or neglect to send their specimens at all, and when they were sent they would arrive at all hours of the day and in every conceivable kind of container, from a four-dram vial to a twelve-ounce cod-liver oil bottle. In many instances there would be no name or date on the package and no possible way of ascertaining from whom it came. Finally, in the belief that lack of system on my own part was largely responsible for the existence of the same fault among my patients, the following plan was adopted, with most satisfactory results. A number of wide-mouthed, glass stoppered, four-ounce bottles were obtained and labeled as follows: IMPORTANT.— Take specimen from *mixed*, evening and morning urine, and deliver before noon on WEDNESDAY. Amount in 24 hours . . ; name . . . . ; address . . . . ; date . . . . When a patient is first seen she is given an empty bottle and told to bring or send it to the office on the following Wednesday before twelve o'clock, filled and with the blank spaces on the label properly filled out, and to send a specimen in the same way on the first Wednesday of every month until she is directed to do otherwise, which, of course, will be at the end of the seventh month when weekly examinations are begun. When the specimen is left at the office the bearer is given in exchange an empty bottle, freshly labeled, for the following month or week as the case may be.

A list is kept of all specimens due to arrive on a given Wednesday so that delinquents may be notified at once by mail or messenger. The plan has been surprisingly successful, for it insures a clean bottle, a sufficient amount of urine for examination and more than anything else, it impresses on the patient's mind the importance of sending the specimens regularly and promptly.

It seldom happens that all the bottles are not in the office by ten o'clock on Wednesday morning and by having them all together in this way the work of examining them is, of course, lessened to a marked degree. As the analyses are all made in the physician's office and at one time it is more convenient to record them in a book and to make no note of the result on the history card unless abnormalities are found.

Another point to which I wish to refer has to do with the maintenance of absolute asepsis from the beginning to the end of labor. Aseptic solutions are in constant demand in the lying-in-room and the most painstaking care in the disinfection of the hands and instruments will amount to nothing, if, for any reason, the parturient canal or any part of it require douching or cleansing and an ample supply of sterile water is not at hand. Boiling water can usually be had in sufficient quantity, but it frequently happens that there is not time for it to cool down to a suitable temperature and cold water from the faucet is, of necessity, added to it. To obviate this difficulty I have provided myself with a number of wooden boxes with stout leather handles each of which contains four half-gallon bottles of distilled water, one pint of boric-acid solution for the infant's eyes and mouth immediately after birth; one pint of standard sterile salt solution for infusion; three agate basins or trays, one for sponges, one for towels and one for receiving the placenta with the gush of blood that follows it, and a two-weeks' temperature chart for the nurse's use. One of these boxes is sent to each patient three weeks before labor is expected and the slight trouble expended in making it ready is more than compensated for by having it at hand when the woman is delivered. There is never any doubt as to the absolute sterility of the solutions, and the trays are of the greatest convenience in that they are of a size and shape exactly suited to the requirements of the case.

The subject of obstetrical bags has been pretty thoroughly exhausted and I have only one point to raise in this connection. Every labor is, in a sense, an emergency case for it is impossible to predict the exact hour or even day when the summons will come. Consequently, it is extremely difficult to be in constant readiness, both by day and night, to respond at once to such calls. Moreover, a second case may, and by a curious coincidence often does, follow so closely upon the first that the physician has to go directly from one patient to another with the least possible delay. For this reason any form of bag which necessitates preliminary sterilization of instruments at the obstetrician's house is apt to be decidedly unsatisfactory. If a second case calls for immediate attendance, or if an instrument or suture is in any way rendered septic, the means of rapid and effective resterilization should always be available.

On this acount I have discarded every form of so-called aseptic bag and carry nothing sterile to my cases except operating gown in a muslin case, gauze, cotton, cord dressings and sutures of silk and catgut. Instruments and silkwormgut, if it is needed, are boiled in a long narrow copper tray of such size and shape that it will hold any obstetrical forceps together with cord, scissors, catheter, douche-tube and any other instruments that may be required in special instances, covered with the minimum amount of water, to secure rapid boiling. If when needed they are too hot for use, they may be cooled by the addition of some of the distilled water to which reference has already been made. By this plan, the physician is absolutely independent of his outfit and, if necessary, can go from one patient directly to another and do equally good work in both cases.

269 West 138th Street.

Dr. Jacobi Honored.—At the recent commencement of Columbia University Dr. Abraham Jacobi was honored with the degree of LL.D.

MEDICAL PROGRESS.

Pneumothorax and Whooping-Cough.—F. Nilly (*Med. Chronicle*, May, 1900) reports the case of a child seriously ill with whooping-cough and diphtheria in whom the pulse-rate averaged about 145 and the respirations about 70 or 80 for several days with consequent marked prostration. The only physical signs obtainable were an uncertain hyperresonance at the left base, with distant breath-sounds approaching the bronchial type just within the angle of the scapula. An exploratory puncture demonstrated the presence of air and on the next day a considerable quantity of gas was evacuated, but no pus was found. The differences in the pharyngeal signs at the two bases had disappeared next day and the child made a steady subsequent recovery.

Treatment of Abortion.—A large percentage of the cases of chronic pelvic inflammation can be traced to a neglected or improperly treated abortion, writes J. S. Baer (*Obstetrics*, May, 1900). In threatened abortion, if seen early, give morphine and keep patient in the recumbent posture with hips raised until all danger is past. Then give fluid extract of viburnum prunifolium and forbid excitement or excessive physical effort during the period of gestation. Do not use a vaginal tampon. If abortion is inevitable, with profuse hemorrhage, dilated os, and the membranes or fetus presenting, and the patient having nervous chills or fever, give a dose of valerian and tampon the vagina. This latter stimulates uterine contraction and favors separation of placenta and membranes, and expulsion of fetus by retained blood. Remove tampon in twenty-four hours, and, if necessary, tampon again for the same length of time. If uterus is not emptied, operative measures are indicated. In complete abortion with expulsion of the fetus, but retention of placenta or membranes, try the tampon, if at about the fourth month and there is no fever or odor. However, if fever or fetor, the uterus must be emptied at once, and best by the curette under anesthesia. The forceps are introduced, the blades separated, and one blade used as a curette; the uterus is then irrigated, and it and vagina packed lightly with iodoform gauze. Then give ergot, continue antiseptic douches, and keep patient in bed as long as if labor were full term.

Hydatid Cysts of the Liver.—These may be unilocular or multilocular, says F. P. Henry (*Proceedings of the Patho. Soc. of Phila.*, May, 1900), the latter, the rarer variety, being hard and firm, and composed of a fibrous tumor enclosing space with clear gelatinous contents, in which the cysts are found. The infection is rare in this country, but is common enough in Iceland and Australia, where careless habits of cleanliness prevail, and the inhabitants live in close contact with their dogs. The dogs become infected from eating the flesh of sheep and oxen. The tænia develop in the dog's intestine, are about a quarter of an inch long, and are usually transmitted to human beings from the dog's tongue. The microscopic examination of the cyst-contents shows granular detritus, cholesterin crystals, and the characteristic hooklets.

Podalic Version.—The dangers of this operation to the mother, says D. S. Hanson (*Cleveland Medical Gazette*, June, 1900), are rupture of the uterus, sepsis, shock, hemorrhage, laceration. Rupture of the uterus should not occur if any liquor amnii remains, and sepsis may be avoided by strict cleanliness. The dangers to the child are interference with circulation due to pressure on cord, embarrassment of respiration by attempts of child to breathe before its head is delivered, so drawing liquid into its lungs, injury to nerves by traction on neck, and fracture of humerus. Yet in spite of these dangers, version is usually to be preferred to a forceps-delivery, as being easier, less dangerous, and more effective.

Slight Fever During Puerperium.—Slight elevations of temperature during the puerperium occur oftener by half in primiparæ than in multiparæ, and are usually due, says K. Franz (*Centralbl. für Geburtshülfe und Gynäkologie*, translated for *Obstetrics*, May, 1900) to the retention of the products of saprophytic bacteria in the uterus. These bacteria are probably identical with the saprophytes of the vagina, and are often present in the normal uterus; they give no symptoms so long as there is free vent to their secretions. Internal examination tends to produce slight fever only by causing vaginal abrasions, and thus furthering the development of the normal vaginal bacteria. Long duration of labor, or of the expulsive stage, and premature rupture of the membranes have little influence, but diminishing the duration of the third stage tends to produce slight fever.

Actinomycosis of the Lower Jaw.—This condition was acquired by a tooth-brush maker, according to Guinard (*Bull. et Mém. de la Soc. de Chir. de Paris*, T. 26, No. 6), in the following manner: Hogs' bristles were first washed, then taken into the mouth in order to stick them into the handle-holes in bundles. The suggestion is hence wise that these brushes be boiled before using them for the first time.

Cecal Actinomycosis.—In two of three cases, reported by Hofmeister (*Beitr. z. klin. Chir.*, Band 26, Heft 2) microscopical examinations made the diagnosis probable, in the third absolute. The remarkable sign in each was a sharply-defined local movable mass, which the author regards as strongly indicative of the disease. In one a section of the colon was removed and an artificial anus made, which soon healed. In the others a resection of the cecum, appendix and adjoining small and large intestine cured.

Value of Bromopin.—While the action of the bromides of the alkali metals in general is satisfactory, the administration of large doses is often

followed by bromism, so that J. W. Frieser (*Klin. therap. Woch.*, May 27, 1900) finds it advisable to draw the attention of physicians to a new compound, bromopin, made by the action of bromine on oil of sesame and containing 10 per cent. of the former. Bromism has never followed its use in his hands whether a single large or repeated small doses were given. It appears that the drug passes the stomach unchanged, to be absorbed in the small intestine and to be deposited in the tissues like other fats, the bromine only gradually being liberated. Its oily taste is sometimes objectional, in which case it may be given subcutaneously. In appearance and odor it hardly differs from the pure oil of sesame.

Investigation of Sulphocyanates.—G. Treupler and A. Edinger (*Münch. med. Woch.*, May 20 and 29, 1900) say that the presence of sulphocyanates in saliva, urine and milk is not accidental but must be looked upon as a result of normal metabolism, following the decomposition of adenin, a substance allied to uric acid. The authors have found their properties singularly nil, despite the fact that they have been accredited with strong antiseptic powers. They have injected rabbits subcutaneously with the potassium salt without interfering in the least with the animals' well-being. Bacteria were hardly restrained in their growth. Tuberculous guinea-pigs which were subjected to sulpho-cyanate injections showed no improvement. Rabbits, who had received injections some time before they were rendered tuberculous, reacted somewhat more favorably since no tuberculous deposits developed in the chest organs and in the diseased areas it appeared as if a slow healing process went on. But a cure never took place and some animals succumbed even more rapidly with the injections.

When to Operate in Appendicitis.—J. B. Murphy (*Internat. Jour. Surg.*, June, 1900) says that if all acute infective cases of appendicitis were operated upon inside of twenty-four hours the maximum mortality would be within 2 per cent. No man can tell within the first twenty-four or forty-eight hours what the further progress of the case will be; the danger to life and the period of convalescence increase with the length of time between the onset and the operation; therefore, the most rational thing to do is to operate within the first twenty-four hours.

Juvenile Neurastheuia.—C. L. De Merritt (*N. Y. Med. Jour.*, June 16, 1900) urges the importance of recognizing symptoms of neurasthenia and hysteria appearing in children, for he believes that a majority of such cases among adults have their insidious beginning in childhood. Heredity is both a direct and indirect factor. By the latter is meant that neurotic parents scold and nag their children incessantly, yet have not the will-power to enforce real discipline, thus destroying the mental equilibrium of their offspring. Overstudy is not the chief factor in causing school-children to "break down." German children study harder than ours, but their home-life is more sedate and precocity is suppressed, not encouraged, and collapse is much less often seen. Lack of out-door exercise is a prolific cause of neurotic troubles. The frequent symptoms observed are nocturnal terrors, marked insomnia, great irritability, a tendency to lie and impose on people for no apparent reason, masturbation, fits of crying, habitual feigning of illness and undue love of sympathy. With reference to treatment the parents must first be scrutinized. If they are neurotic or hypochrondriacal it must be explained how such defects react upon the child and thus furnish the greatest incentive to overcome their own deficiencies and a double cure may result. Drugs are of secondary importance. Bromides and hyoscyamus may be temporarily used. Warm sponge bathing at bed-time is of use. In mild cases the child will oftentimes do much better in school, for the withdrawal of the child from companionship and the relaxation of mental discipline may have a most unfortunate effect and produce, instead of a cure, a young hypochrondriac.

Tetanus Treated by Antitoxin.—J. F. Clarke (*N. Y. Med. Jour.*, June 16, 1900) reports a case of tetanus developing after a serious crushing accident to the hand, although prompt antiseptic treatment was given. Seven days later the first symptoms of stiffness of the jaws were noticed, but, owing to difficulty in getting the serum, it was not used until the next day. In about twelve hours there was apparent marked improvement, the jaws being so much relaxed that the tongue could be protruded about one inch. After each injection the pulse became slower and stronger. A few hours later, however, the patient started suddenly from sleep calling for air, the pulse became imperceptible and he fell back in syncope. Although temporarily revived, he soon after died suddenly, the pulse failing before respiration.

Typhoid Infection of Uterus.—A. J. Lartigau (*N. Y. Med. Jour.*, June 16, 1900) has reviewed the cases of Kühnau, Dobbin and Blumer, who demonstrated the presence of the bacillus of typhoid fever in cultures taken from the uterus of patients in the puerperal state. He further reports two cases in detail which he examined thoroughly postmortem and found the typhoid bacilli in the uteri of these cases. One followed the course and presented the lesions of atypical typhoid, but the other was one of that remarkable class of typhoid cases, whose chief interest becomes centered in the absence of any anatomical lesions of the intestine. Both these patients were non-puerperal women and the uteri were practically normal, save for a little congestion and thickening of the mucous membrane, especially of the fundus. The bacilli were found in the urine of the second case, but the author believes that the infection of the uterus in both cases took place from within.

Thoracic Sympathetic Disease.—J. Fraenkel

(*Med. Rec.*, June 16, 1900) reports an interesting and rare case. The patient was under close observation by the author for nearly one year, and a detailed record of the symptoms from time to time is given. The history seems to be that of a true hysterical case with attacks of pain in the left arm, leg and left side of the face and also at times severe pain in the cardiac region. Repeated physical examinations failed to disclose any abnormality or lesion and the diagnosis of hysteria was made. The patient finally entered a state of acute collapse, became pale, covered with perspiration, the features were pinched, the head was drawn to the left side, and there was an enormous distention of the abdomen. The pulse was about 120 and the temperature only slightly elevated. The patient died and the autopsy showed no important lesion except that the four upper thoracic ganglia of the left side and the intermediary trunks were buried in a mass of purulent material beneath the parietal pleura. The right inferior cervical ganglion was also surrounded by purulent matter. A thorough examination of the cord to determine the source of the pus was not allowed. What relation this anatomical finding had to the clinical picture of hysteria, it is impossible to say. The nerve-cells of the ganglion were very little affected, the pus-cells, together with the staphylococci, streptococci and bacilli which they contained, being massed outside the ganglion-sheath and infiltrated but slightly.

Plantar Reflex.—The so-called Babinski's phenomenon, which is a deliberate, marked extension of the great toe, with or without extension and separation of the other toes, when the sole of the foot is stroked, we have never found, say G. L. Walton and W. E. Paul (*Jour. Nervous and Mental Dis.*, June, 1900), in normal individuals. The plantar reflex with flexion of the toes is absent in ten per cent. of normal persons and in nearly twenty per cent. is unilateral. The infantile plantar reflex varies in the same child, at one time the toes being extended, at another time flexed. In lesions of the pyramidal tract, as in hemiplegia and diplegia, the normal flexion reflex is replaced by the Babinski phenomenon, but this latter was also present in one case each of general paralysis, meningitis, hydrocephalus, uremia, and alcoholism. However, in each of these cases there was some evidence pointing toward pyramidal tract disease, and the authors conclude that the presence of the Babinski phenomenon establishes a pyramidal tract lesion with almost absolute certainty. Its absence, however, does not exclude pyramidal disease, as it was not present in two of four cases of lateral sclerosis, one of two syringomyelia, and in a small proportion of the cases of ataxic paraplegia, myelitis, combined system disease, and trauma. The sign may be elicited in the unconscious state and is absent during convulsions. It is best brought out by a deliberate and even stroke from the heel toward the toes with a not too sharply-pointed orange stick. Babinski's phenomenon is often the earliest reflex to appear and it may persist when other reflexes, such as knee-jerk and ankle-clonus, are absent.

Massage in Recent Fractures.—W. H. Bennett (*Lancet*, June 2, 1900) believes early massage and passive motion to be most important elements in the rational treatment of fractures. Massage relieves the painful muscular spasm, expedites the absorption of extravasated materials, and prevents muscular atrophy; passive motion prevents the painful joint stiffness and adhesion of the soft parts to the site of fracture, and the two together keep the limb in such condition that, as soon as firm union occurs, it returns to full and comfortable function. Taking a fractured leg as example, one first reduces carefully the fracture and then applies a posterior splint with a proper oblique footpiece. After smooth muscle massage for ten minutes, lateral splints are attached. In massage one hand grasps the upper end of the bone while the other is applied to the lower end and is pushed slowly, steadily and gently upward. This is repeated for ten minutes, relieving pain and spasm, and often causing the patient to fall asleep. This massage is repeated every day. At the end of three days passive motion is begun, first with the toes. After the fifth day the ankle may be unbound and passive motion performed, while the other hand steadies the site of fracture. For the passive movement three to five minutes at a sitting are sufficient, but this must invariably be preceded by a quarter of an hour's smooth massage. At the end of two weeks the knee may be given passive motion. At the end of three weeks complete ordinary muscular massage may be carried out, and the leg allowed to be without splints in bed. The nearer the fracture is to a joint, the more important is the massage. The advantages of the treatment are: The ease with which the patient is relieved from muscular spasm and pain; the rapid absorption of effused blood; the prevention of stiffness; the preservation of the normal nutrition of the limb; the shortening of the time by half during which the patient is prevented from having full use of the limb.

Forced Abortion.—When abortion is indicated during the first three or four months of pregnancy, owing to incontrollable vomiting, heart-disease, etc., writes L. Merle (*L'Obstétrique*, May 15, 1900), the extemporaneous dilatation of the cervix, followed by the immediate extraction of the fetus and the clearing out of the uterine cavity is the process of choice. The patient is placed under chloroform, the cervix drawn down, and while the left hand presses on the fundus through the abdominal wall, metallic dilators, preferably those of Hegar, are inserted. When the dilatation is sufficient, which should be in twenty to thirty minutes for a multipara, and up to an hour for a primipara, introduce one finger, or, if possible, two fingers, rupture the bag of

waters, break up the fetus, and extract it. The curette need hardly ever be used. Then with a hard sponge soaked in bichloride or creosoted glycerin, swab out the uterus thoroughly, give an intra-uterine douche of bichloride, and tampon with salol or iodoform gauze. Performed thus, abortion becomes a sure, harmless, simple and easy operation.

Portable Orthopedic Apparatus.—A. Schanz (*Archiv f. klin. Chir.*, Band 61, Heft 1, p. 114). The knowledge of the underlying principles of mechanical orthopedic treatment is a necessity for the average physician. When unfavorable results of its application have appeared doubtless improperly-designed or fitted braces have been at the bottom of the trouble. There is one way only to avoid this, namely, due understanding of the kind, degree and end results of the essential pathological conditions and of the mechanics by which the apparatus applied may act in correction. Thus, the lesions in active progress and in fixed deformity constitute the great indications for management. Again after the establishment of the final deformity the disease may be renewed so that in the one patient both clinical pictures are exhibited. Scoliosis in modern pathology might be defined as a disproportion between the rigidity and elasticity of the spine when the process is active; but, when the deformity is complete, as a deforming of the spinal column and especially the trunk skeleton. In the former case we seek to restore the relation, in the latter to correct the deformity; both may be carried on together or be taken in series according to the case. All orthopedic appliances may be divided into three classes. In the first group all such traction devices which may be likened to garters. These take their upper support over the shoulders and their point of resistance from the lower part of the trunk or the clothing. The pull thus exerted always tends to increase the deformity by simply approximating the points of attachment. These instruments are the oldest type and are to be condemned. The principle underlying the second series of apparatus is that of lifting the weight of the shoulders and head, either or both, upward by braces and plates taking their point of advantage on the pelvis. In this class belong all types of appliance which do not seek also to correct deformity. Such as combine support and correction, belong to the third lot, most modern and approved. They all possess screws, bands, pads, braces and such contrivances for overcoming the displacements and for imposing their own upon the body outline. The purely supportive devices have a wide field and may be used in many cases, provided the patient be under massage, light gymnastics and breathing exercises, to prevent the atrophy of rest which might cause an accentuation of the disease by removing some of the support of the corset or jacket due to the falling of the body away from it. It is impossible in any portable device to secure the same amount of extension and correction as in the stationary. It is beyond the powers of the soft parts to stand the strain of overcorrection by any apparatus, which would, indeed, be the full indication to carry out. But by the careful application of the third kind of brace much can be done. They may be made to act in scoliosis by rotation or torsion and by side pressure, as well as by the usual extension and vertical support from below. Pads properly placed along the rib-angle will correct much lateral deformity and adjustment most carefully of each device to the evident lesions will make this form of treatment far more efficient.

Gun-Shot Wounds.—Experiments have been undertaken in this subject by Kayser (*Beit. z. klin. Chir.*, Band 26, Heft 2) with the following conclusions: There is no destruction of infective matter adherent to the projectile; the length of the flight is not a factor; that in spite of penetrating obstacles the bullet may be infectious; that this may not be the case when the resistance and depth of penetration have been considerable: after traversing dirty material the bullet is always infectious in spite of any other body pierced afterward; all wounds are theoretically infected though practically the body-resistance makes this danger slight. Nevertheless the open treatment of all wounds is the safer and better for both practical and theoretical considerations.

Retropharyngeal Abscesses.—Small difficult central or lateral foci in this region are approached, evacuated and drained very successfully by Schmidt (*Deut. Zeitschr. f. Chir.*, Band 55, Heft 1—2) as follows: The incision is along the inner border of the sternocleidomastoid muscle, which is strongly retracted after exposure, and the path to the retropharyngeal space is made outside of and behind the internal jugular vein.

Pathology and Therapy of Basedow's Disease.—Despite the many researches on thyroid disease, there are many important factors concerning exophthalmic goiter which have to the present time defied the investigators. F. Dinkler (*Münch. med. Woch.*, May 22, 1900) describes a unique case in which all the symptoms were extreme and were accompanied by grave nervous disturbances such as choreiform movements, hemiparesis and psychical changes. Similar cases had previously been carefully examined with the view of finding anatomical lesions in the nervous system to explain the symptoms, but without success. The author, however, by a modified Weigert stain has been able to demonstrate a degenerative process in the motor area and tract and thinks that this is the rule in Basedow's disease. The thyroid gland he has found to consist of solid acini packed with cells and with but little interocinous connective tissue between them, in which there may be cell-masses resembling the newly-formed canaliculi of cirrhosis. In other severe cases these changes were less marked, but the thymus showed a lymphatic

hyperplasia. It is possible that in these patients the thymus possessed functions similar to those of the thyroid especially since it has been previously discovered that both have an analogous physiological action when taken internally. In both sets of cases a well-developed dilatation of the capillaries and venules was found. The surgical treatment of exophthalmic goiter has come into vogue and by it life has been saved in some severe cases; on the other hand, in many the prognosis has been rendered more serious by surgical intervention. The author thinks the time has not yet come to definitely decide upon the indication and value of hemi-extirpation.

Nasal Reflexes.—Some years ago Rosenberg advocated cocaine spraying of the nasal mucosa before general anesthesia in order to prevent the irritation of the nerve-endings of the trigeminus nerve; which latter occurrence frequently called forth inhibition of the vagus and of the respiratory center in the medulla oblongata. If the cocainizing is properly done, said Rosenberg, these reflexes are not called forth and so the giving of an anesthetic, chiefly chloroform, is made much safer. F. Bruck (*Berlin. klin. Woch.*, May 14, 1900) now comes forth and denies that the cocainized parts of the nasal mucous membrane become anesthetic and, furthermore, that such a process never extends to the entire mucosa. Bruck finds three minutes after such cocainizing that the membrane still reacts to irritation. In not a single instance of the many trial cases did he obtain "certain and complete anesthesia," as maintained by Rosenberg. Bruck claims that the cocaine can only act upon a membrane free from mucous secretion. Therefore, would it be absolutely necessary to use rhinoscopy in order to clear completely the nose of its mucous secretion before cocainizing. However, there are so many crevices and corners and folds in the nasal mucosa, which it is practically impossible to reach with the spray, that a complete cocainization of the lining membrane of the nose is virtually impossible. That the marked decrease in the activity of the reflex occasioned by only a partial anesthesia of the mucous membrane diminishes the danger of chloroform narcosis, Bruck admits; but would it not be better and simpler, declares he, in order to prevent the irritation of chloroform vapor on the nasal mucosa, to stop both nostrils with cotton during anesthesia? He agrees fully with Rosenberg in the statement that the chloroform vapor awakens a reflex from the nasal mucous membrane which affects both the vagus and the respiratory center. The experiment which was made confirmed him in this view. A rabbit was chloroformed at first through the nose and later entirely through a tracheal cannula. At first both breathing and pulse-rate were deeply affected, whereas in the later attempt both remained perfectly normal. If the nostrils are occluded with cotton it certainly becomes a more difficult feat to administer chloroform for the mouth-breathing must be most carefully watched. Extraordinary care must be exercised to prevent the falling-back of the tongue during the narcosis. Meanwhile, in the light of further investigation, it may possibly be found that this increased difficulty of technic is more than counterbalanced by the extreme danger that chloroform anesthesia assumes when the vapor is allowed to act on the nasal mucous membrane.

Case Mistaken for Aortic Aneurism.—Although aortic aneurism is the most usual form of mediastinal growth, almost typical signs of that condition may sometimes be mistaken, as shown by a case reported by F. Griffith (*N. Y. Med. Jour.*, June 2, 1900). The patient was followed for about fifteen months, gradually developing signs and symptoms of pressure in the mediastinum. Marked dulness, pulsation and thrill were present over the anterior upper and left chest. Pain was sharp and lancinating. There were dyspnea, dysphagia, whispering voice, paralysis of left vocal cord, sharp cough, and unilateral symptoms of sweating and edema. Radial pulses and pupils were unequal and tracheal tugging was present. A radiograph taken gave negative results. The temperature ranged between 97.4° and 99° F. There were no night-sweats, excepting at times on the head. Dulness over the left apex seems to have been the only sign of pulmonary trouble. The autopsy showed the upper half of left lung collapsed and its position occupied by a large tuberculous cavity, containing about three ounces of bloody fluid holding cheesy masses. A large mass of mediastinal glands, the size of two fists, was present, in which were imbedded the arch of the aorta, the esophagus and bronchi. The heart was normal but small and the aorta was intact.

Therapeutic Advantages of Ferratogen.—Ferratogen differs from all other organic iron compounds in the peculiarities of its manufacture. As stated by M. Cloetta (*Münch. med. Woch.*, May 29, 1900), yeast is grown on a medium containing iron; the nuclein thus formed is isolated, digested with gastric juice and washed with alcohol containing some hydrochloric acid. There results an insoluble yellowish powder which is not affected by gastric juice and which contains as much as one per cent. of iron. Although pancreatic digestion in vitro is slow, it is well absorbed in the living small intestine. The author considers absence of gastric irritation the most important property of a ferruginous preparation and thus awards a high rank to ferratogen, since this passes the stomach without change.

Neurasthenia and the Rest Cure.—The employment of the rest cure for nervous complaints is rapidly increasing. Establishments for this trouble are springing up in great numbers. Besides those who have taken the treatment under professional advice, numbers are met with who have done so at the solicitation of friends or at

their own discretion. F. A. McGrew (*Jour. Am. Med. Assoc.*, June 9, 1900) fears that this useful form of treatment will come into disrepute unless there is a more definite knowledge of its proper use and limitations. To this end there must be a working scientific basis substituted for the present haphazard way of disposing of troublesome neurasthenic patients. The writer classifies neurasthenia under three heads, *viz.*: (1) Developmental neurasthenia. (2) Overstimulation neurasthenia. (3) Developmental plus overstimulation neurasthenia. Developmental neurasthenia occurs in persons who have a constitutional nerve weakness from the cradle up, and in those who inherit the neurasthenia from degenerate parents. Sometimes it is due to some adverse influence during fetal life; to some disorder of nutrition during the developmental period; to some accident of labor; to unhealthy environment and habits during the formative years of childhood. In these nervous children there is an instability and imperfect balance characterizing the activity of the brain and cord, and while they are unable to sustain prolonged exertion, there is often an unusual cleverness of thought and action. The person, who eventually suffers from developmental neurasthenia, is usually remarkably healthy in appearance, but complains of chronic fatigue. The symptoms are numerous, various and indefinite, but are all associated with exertion and the fatigue following it. She appears well-nourished but her muscles are flabby, her respiration insufficient, her heart-action weak; she has a languid air, and, in short, her nerves and muscles are without tone. It is very evident that such a patient does not need rest, but exercise to develop and strengthen every part of her system. A course of physical training should be instituted gradually and carried out very carefully. Hydrotherapy and massage should be added to the physical culture, and a change of diet and surroundings is beneficial. Overstimulation neurasthenia occurs in persons who are born with normal nervous strength, but whose habits of life end in the exhaustion of their inherited nervous vitality. To this class belong the business man who has much worry, sleepless nights and hurried days, until the brain tires and the nerves are irritable. Those who are underfed and overworked, those who are always "on the go," and, in fact, all who overwork in any way are apt to suffer finally from overstimulation neurasthenia. Nervous prostration is the result when the collapse at last comes. In such cases complete rest is needed and food for the wasted tissues. The rest cure is the treatment *par excellence* for the neurasthenic of habitual overstimulation. In addition to complete rest and feeding, there should be given some sedative and nutritive treatment consisting of general massage with passive movements, abdominal massage, hot spinal fomentations, saline spongings and general faradism. The writer discusses the treatment of some of the more frequent symptoms of this form. The third class of neurasthenia consists of a combination of the first two. The treatment of this form is indicated by the prominence of the developmental or the overstimulation element, and often a judicious combination of exercise and rest is necessary.

Surgery of Acute Rheumatism.—A. T. Bristow (*Brooklyn Med. Jour.*, June, 1900) believes rheumatism to be an acute infectious disease and, therefore, in many cases it demands surgical treatment. Where there is much effusion into the joints the absorbed toxic products cause the serious constitutional symptoms. Not infrequently the toxemia is less prominent, especially in the chronic cases, but the injury to the joint surfaces is greater. Therefore, there may be two distinct reasons for surgical interference in rheumatism; an obstinate effusion which intoxicates the system; or a chronic effusion which endangers the usefulness of the affected joint without causing much systemic disturbance. A third reason would exist if we could show that prompt drainage lessens the chances of heart lesions. The only statistics on the subject are those of O'Conor of Buenos Ayres, whose results have been so good that he has abandoned medication and now opens and drains a joint as soon as the diagnosis is made. Bristow believes this to be too radical, but proposes surgical interference in those cases in which operation is the patient's best chance and in which it is more dangerous to wait than to operate, and in those chronic cases where it is worth while to assume some risk to restore the patient's earning capacity.

Cholecystectomy.—C. L. Gibson (*Med. Record*, June 9, 1900) calls attention to the advantages of cholecystectomy under certain conditions. He believes this operation to be indicated in all cases of cholecystitis with or without stones, provided the bile ducts are not obstructed, and that the bladder itself can be removed without too great difficulty. It is also to be done even in difficult cases when the bladder is so situated or so retracted as to prevent safe drainage after incision, and also a prophylactic measure against malignant disease in the presence of long-standing irritation. The gall-bladder is of little physiological importance. Its extirpation under the above conditions presents the following advantages. It is safe and usually not difficult; convalescence is brief and devoid of the discomforts of discharging bile; biliary fistula is prevented; the cure is radical, for the disease focus is abolished; the attacks of pain often recurring in diseased gall-bladders after cholecystotomy are avoided; the pains and digestive disturbances due to adhesions with other viscera are avoided.

SATURDAY, JUNE 23, 1900.

SMALLPOX IN THE UNITED STATES.

DURING the four and one-half months from January 1st to May 18th there occurred, according to the official reports of the United States Marine Hospital Service, more than 10,250 cases of smallpox in the United States. This is about one and one-half as many cases of the disease as were reported during the corresponding period of last year. We took occasion at that time to give a word of warning with regard to the spread of the disease. The warning seemed, perhaps, more pertinent to Northern and Eastern readers, since the series of epidemics in Pennsylvania and in Virginia were the features that attracted general attention. This year, however, the prevalence of smallpox at many widely separated points throughout the country makes obvious the necessity for a determined, universal effort for its eradication. Severe epidemics in Louisiana, Tennessee and North Carolina, have served to swell the statistics quoted, but the reports show that there are dangerous foci of the disease more widely distributed than formerly, and as the prosperous times make communication between different parts of the country more intimate than ever before, the peril from the farther spread of the disease is greatly increased.

The fact that the great body of general practitioners of medicine at the present day have no personal familiarity with smallpox accounts largely for the proportions the present epidemic has attained. Diagnosis is apt to be made comparatively late in the disease. Not only that, but suspicions of the character of the affection under treatment is aroused only when it is well developed. During the preliminary stage, before the characteristic eruption manifests itself, smallpox is conceded to be but slightly contagious. If suspicion of the character of the disease is awakened before the exanthematic period, even although final diagnosis may not be possible, the spread of the affection will be practically prevented by keeping the patients segregated from friends and others. Care in this matter and more active attention to vaccination in adult-life will undoubtedly stamp out the disease completely in a few years.

Up to the time when influenza became endemic in this country there were certain symptoms of beginning smallpox that had much more diagnostic significance than they now have. The splitting headache, the intense backache and the abrupt high fever, so characteristic of the onset of the affection, were pathognomonic of smallpox. The old text-books had it that these symptoms occurred in all the infectious fevers, but not with the intensity or suddenness they develop in smallpox. Certain epidemics of influenza, however, present these symptoms quite as characteristically. He would be an extremely confident diagnostician who in our day would pronounce a case to be smallpox *sine exanthemate* on the strength of these symptoms alone, even although other cases of smallpox were in the neighborhood. Such a diagnosis was thought justifiable, however, twenty years ago and these symptoms must at least always awaken suspicion of smallpox whenever sporadic cases have been reported in the immediate vicinity.

Preliminary rashes are frequently noticed in smallpox cases, and should arouse suspicion of the nature of the disease under treatment, especially if abrupt febrile temperature and severe aches are coincident. These rashes are erythematous and are spoken of as scarlatinaform, sometimes morbilliform in character. That resembling scarlatina rash is most common and occurs especially on the lower part of the trunk, in the groins, and along the sides of the trunk, espe-

cially in the axillæ. As true scarlatina also frequently appears first in these locations it must be excluded by the history. Unlike measles scarlet fever seldom recurs, so that the history of one attack conveys definitive information. The preliminary erythema of smallpox often follows the course of certain nerves. It has been noted in certain epidemics to occur especially on the external surface of the leg, affecting particularly the skin over the extensor hallucis muscle. A pathognomonic preliminary rash is pointed out by certain German observers. It consists of red hemorrhagic spots that are found especially in what is called the leg-navel triangle, that is, in the space included within imaginary lines drawn from a point between the knees to meet a line passing horizontally through the umbilicus. These spots blanch slightly on pressure, but do not disappear. Unfortunately, this eruption, which often occurs two or three days before the general macular eruption of smallpox, is not found in all, but only in somewhat less than one-half the cases. In certain epidemics, however, it is very constantly present.

Two diseases are likely to be confounded with smallpox in its initial stages. They are measles and chicken-pox. The eruption of smallpox begins with maculæ that are not unlike those of measles. To realize more thoroughly this similarity of beginning, it is only necessary to recall that for centuries the two diseases were confounded. The initial fever and aches of measles are less than those of smallpox, while the catarrhal symptoms are much more severe. Chicken-pox is usually easy to differentiate, but in exceptional cases the resemblance is very marked. Severe chicken-pox has often been mistaken for mild variola in the old days of the prevalence of smallpox. In recent years even experts have been known to diagnose mild smallpox as chicken-pox. The Vienna school has never given up the contention that the two diseases are essentially the same. Professor Senator in Berlin says that the introduction of a case of smallpox into Berlin is usually followed by an epidemic of chicken-pox. Varicella, to his mind, seems to be a variola modified by generations of vaccination and better hygienic surroundings with increased resistance to disease invasion. The pathognomonic distinction between varicella and variola is the fact that, at an early stage of varicella, lesions in all stages, macular, papular, vesicular, clear and cloudy, are to be found. In smallpox the lesions are simultaneously in the same stage, as a rule.

If attention were paid to the exact and immediate diagnosis of cases that may prove to be smallpox the spread of the disease could be absolutely limited. The present state of affairs—an increasing mortality from smallpox—is due to two things that the physicians of the country have it in their power to remedy. The one is, as we have said, lack of assurance in diagnosis; the other is the neglect of renewal of vaccination among adults. It will not require much attention to eradicate both evils if the work is taken up seriously. Let us begin the twentieth century in a manner worthy of the hundred years of vaccination that have just been accomplished.

The courts are steadily lending their support to health boards and school boards in their insistence on the necessity of vaccination. In Philadelphia at the present time a citizen is testing before the courts the right of the public school officials to compel all pupils of the public schools to take such precautions as they may prescribe. The Supreme Court of the State of Pennsylvania rendered a decision in a similar case in 1894 in which the subject was discussed as follows:

"It should be borne in mind that there is no effort to compel vaccination. The school board do not claim that they can compel the plaintiff to vaccinate his son. They claim only the right to exclude from the schools those who do not comply with such regulations of the city and the Board of Directors as have been thought necessary to preserve the public health.

"Is the regulation now under consideration a reasonable one? That is to be judged of, in the first instance, by the city authorities and the school board. It is only in the case of an abuse of discretionary powers that the Court will undertake to supervise official discretion. Vaccination may be or may not be a preventive of smallpox. That is a question about which medical men differ and which the law affords no means of determining in a summary manner. A decided majority of the medical profession believe in its efficacy. The municipal regulations of many, and, I have no doubt, of most, of the cities of this State and country provide for it.

"In the present state of medical knowledge and public opinion upon this subject, it would be impossible for a court to deny that there is reason for believing in the importance of vaccination as a means of protection from the scourge of smallpox. The question is not one of science in a case like the present. We are not required to

determine judicially whether the public belief in the efficacy of vaccination is absolutely right or not. We are to consider what is reasonable in view of the present state of medical knowledge, and the concurring opinions of the various boards and officers charged with the care of the public health.

"The answers of the city and the school board show the belief of the proper authorities to be that a proper regard for the public health and for the children in the public schools requires the adoption of the regulation complained of. They are doing, in the utmost good faith, what they believe it is their duty to do, and, though the plaintiff might be able to demonstrate by the highest scientific tests that they are mistaken in this respect, that would not be enough. It is not an error in judgment or a mistake upon some abstruse question of medical science, but an abuse of discretionary power, that justifies the courts in interfering with the conduct of the school board, or setting aside its action."

AMERICAN FESTSCHRIFTS.

THE idea of a Festschrift seems to have struck almost as simultaneously as forked lightning in three medical centers of America. First, in chronological order of publication, came the Festschrift to Dr. Jacobi which has already received extended notice in our columns. This was promptly followed by a volume of scientific papers emanating from the students of Dr. William H. Welch of Johns Hopkins, in commemoration of the twenty-fifth anniversary of Professor Welch's doctorate. We are just in receipt of a similar volume composed of contributions from the William Pepper Laboratory of Clinical Medicine, the work of men who have received their training in, or are connected with, the Pepper Laboratory.

The Welch Festschrift is a most imposing volume, beautifully bound and illustrated by some of the most artistic work that has ever emanated from Johns Hopkins. The articles themselves cover a wide range of subjects. Many of them are devoted to questions usually classified as pure science, but in the rapid strides of medical progress their observations and conclusions may be assimilated at any time and afford practical working basis for surgical or medicinal therapeutics. Among those devoted to practical subjects may be mentioned: "Urea and Some of Its Physiological and Pathological Relations," by C. A. Herter; "Some Observations Upon the Anatomy of the Gall-Bladder and Ducts," by George E. Brewer; "Experimental and Surgical Notes Upon the Bacteriology of the Upper Portion of the Alimentary Canal, etc.," by Harvey Cushing and Louis E. Livingood; "The Origin, Development and Degeneration of the Blood-Vessels of the Human Ovary," by John G. Clark; "The Gonococcus," by Hugh H. Young.

The presentation of the volume was celebrated at a complimentary dinner held at the Maryland Club, Baltimore, on the evening of May 4, 1900. Not the least interesting feature of the exercises was the description by Professor Councilman, who made the presentation, of the environment in which the work of Johns Hopkins Laboratory has been prosecuted. This has special application to the discussion that is going on just now regarding the New York State Pathological Institute. Dr. Councilman said: "The work has been in a broad field, and the workers have had a clear sky above and fresh breezes around them." These are the essential conditions of success of research work which Dr. Councilman, unfortunately, has been using his influence to suppress in connection with the Pathological Institute.

In the memorial volume of the William Pepper Laboratory, which is also artistically illustrated, we find among the more strictly laboratory articles the following practical subjects: "A Fatal Case of Sulphonal Poisoning," by Alonzo Engelbert Taylor and Joseph Sailer; "The Pathology of the Erythrocyte," by Alfred Stengel; "The Influence of Immoderate Water-Drinking Upon Metabolism and Absorption," by D. L. Edsall; "The Etiology of Appendicitis," by Charles H. Frazier; "The Etiology of Pertussis," by Joseph Walsh.

These volumes would be a most valuable addition to every medical library of the country. The editions are limited, and we have not been informed how generally they may be obtained.

ECHOES AND NEWS.

NEW YORK.

Congress of Scientific Men.—The local committee of the American Association for the Advancement of Science has made elaborate preparations for the reception of those who will attend the convention of the Association this week. The sessions will be held at Schermerhorn Hall, Columbia University, the American Museum of Natural History and the Hotel Majestic. The ex-

ercises will begin at the Majestic Hotel at noon on Saturday, June 23d.

Dr. Banta Reinstated.—Dr. Francis M. Banta has resumed active duty as medical officer of the Fire Department. Dr. Banta, who was appointed a medical officer of the fire force by the Republican Fire Board in place of a Tammany physician, was in turn removed by Fire Commissioner Scannell. The physician appealed to the courts. The Supreme Court ordered his reinstatement. An appeal was taken, and the Appellate Division of the court affirmed the finding of the lower tribunal.

Officers of the County Association.—At the annual meeting of the New York County Medical Association, held Monday evening, June 18th, the following officers were elected for the ensuing year: President, Parker Syms, M.D.; first vice-president, J. Riddle Goffe, M.D.; second vice-president, Emil Mayer, M.D.; recording secretary, Ogden C. Ludlow, M.D.; corresponding secretary, J. W. Draper Maury, M.D.; treasurer, Charles E. Denison, M.D.; member of the executive committee, for 3 years, Frederick Holme Wiggin, M.D.

St. Vincent's Hospital Alumni.—Some thirty graduates organized the Alumni Association of St. Vincent's Hospital on the evening of June 17th, at the home of Dr. Charles H. Lewis, at 47 West Fifty-eighth Street. The officers chosen are: President, Dr. Charles H. Lewis; vice-president, Dr. Charles L. Weeks; secretary, Dr. Joseph A. Dillon. The Association will meet four times a year.

St. Vincent's Motor Ambulance.—The new automobile ambulance of St. Vincent's Hospital, which cost $3000, had its first regular run on June 13th. The power is supplied by a storage battery and the vehicle is equipped with the usual ambulance paraphernalia.

New Hospital for Crippled Children.—The residence of Dr. Angell, Paulding Avenue, on the Hudson River near Tarrytown, has been leased by the Board of Managers of the New York State Hospital for the Care of Crippled and Deformed Children. Changes necessary to equip the building for hospital use will be made at once, and the hospital will be opened early in the autumn. The following physicians were elected members of the Consulting Medical Board: Drs. Francis Delafield, Robert F. Weir, W. Gilman Thompson, Joseph D. Bryant, Lewis A. Stimson, A. Alexander Smith, Reginald H. Sayre of New York, Roswell Park of Buffalo, and L. A. Weigel of Rochester.

Contagious Diseases.—For the week ending June 16, 1900: Measles, 392 cases and 17 deaths; diphtheria, 288 cases and 53 deaths; laryngeal diphtheria (croup), 9 cases and 4 deaths; scarlet fever, 114 cases and 9 deaths; chicken-pox, 47 cases; tuberculosis, 182 cases and 167 deaths; typhoid fever, 32 cases and 12 deaths; cerebro-spinal meningitis, 4 deaths; totals, 1064 cases and 266 deaths.

Tuberculosis Tests of Cattle.—The report of the Tuberculosis Committee of the New York State Board of Health for the month of May, which was submitted on June 19th, shows that among 1075 head of cattle which were subjected to the tuberculosis test, 36 were condemned and 6 destroyed. Since January 1st 1443 head of cattle have been tested, 84 condemned and 52 destroyed. Of the total number tested 1242 were grades or common stock, 80 were Holsteins and 70 Jerseys. About 1000 head of cattle in Syracuse still remain to be tested. Thus far but 1 per cent. has been condemned, which should prove conclusively that the first test, made a year ago, which resulted in the condemnation of about 5 per cent. of the entire number, was well done and that the diseased animals condemned were pretty thoroughly disposed of.

Walter Duryea Leaves Roosevelt.—Dr. Abbé's patient, Walter E. Duryea, left Roosevelt Hospital on June 19th after a stay of ten months. He was taken away in a carriage ambulance from the roof of which his litter was swung by leather slings. A surgeon and a nurse accompanied him. He was taken to Hoboken, where a sleeping-car which had its stateroom window removed awaited him. Mr. Duryea was lifted through this window, litter and all. He was taken to a private sanitarium in Danville. His physicians are sanguine of his ultimate recovery.

PHILADELPHIA.

Health Report.—Deaths in the city for the week ending June 16th were 455, an increase of 44 over those of the previous week and of 32 over the corresponding week of last year. Contagious diseases: Diphtheria, 83 cases, 12 deaths; scarlet fever, 73 cases, 3 deaths; typhoid fever, 40 cases, 13 deaths; smallpox, 1 case.

University Commencement.—The 144th annual commencement of the University of Pennsylvania was held June 13th. Of the 550 degrees conferred, 180 were Doctor of Medicine, 145 Doctor of Dental Surgery, and 11 Doctor of Veterinary Medicine. The address to the graduates was given by Acting President, Wm. L. Prather of the University of Texas.

Diet-Kitchen for Children.—A diet-kitchen for infants and children is being established at the Rouse Mission of the Trinity Episcopal Church, at Thirty-second and Wallace Streets, under the medical direction of Dr. George T. Palmer. Dr. Marcus P. Hatfield will be the consulting pediatrician. The kitchen will be open daily under the supervision of the trained nurses of St. Barnabas Guild.

The American Laryngological, Rhinological and Otological Society.—At the final session papers upon "Nasal Synechia" were read by Drs. Price Brown of Toronto, Can., and M. D. Leder-

man of New York. The former said that synechia are often the result of the rhinologist's trauma. Another cause is the freedom from post-operative pain in many cases, the patient thinking that the operation itself only is of importance and ceasing his visits before healing has sufficiently advanced to prevent the formation of synechia. They should be warned regarding this. The electrogalvanic cautery is the instrument most apt to be followed by synechia, but this statement is not meant to condemn a most useful instrument as some speakers have done. He keeps the parts separated after an operation by cotton-wool or rubber sheeting, gauze not being liked for this purpose. An absorbent cotton tampon has been left in place for ten days without giving distress or becoming offensive. Dr. Lederman uses surgical sponge or spunk for a separating-tampon after operation. This he finds to act well also in controlling hemorrhage.

In the discussion Dr. J. A. Stucky of Lexington, Ky., stated that in his experience more systemic trouble results from the removal of synechia than from any other nasal operation. He prefers keeping the patient in a hospital for two or three days before operating. Dr. While of Richmond uses as a separating material gutta-percha, such as dentists use. This can be molded to any desired shape. The cases that give him the most trouble are the dense osseous synechia high up between the turbinate and ethmoid.

Dr. Wm. H. Dudley of Easton, Pa., read, by invitation, the history of a case of cerebral abscess following chronic otitis media, with recovery after operation. The patient was a Bohemian and but little history could be obtained. As the symptoms warranted operation, the mastoid was opened. The bone was dense and no granulation tissue was found. The skull was then trephined and, after several punctures in the temporosphenoidal lobe had been made, one-half ounce of seropurulent fluid was obtained. This fluid contained pus-cells and broken-down brain-cells. The patient was violent for some days after operation and had to be tied to the bed. On the twenty-eighth day he was allowed to sit up and on the fifty-sixth day left the hospital. This was two and a half years ago. The man's intellect now seems as good as formerly.

Dr. C. P. Linhart of Columbus, Ohio, reported a case of peculiar enlargement of the turbinals. The growth had been pronounced sarcoma by two surgeons. The patient was sent to New York where the whole of the right inferior and part of the middle turbinal were removed, the growth not being thought a sarcoma, however. The wound did not do well and in a few weeks the inferior turbinal on the left side became enlarged. The patient was then given iodide of potassium in increasing doses with almost immediate improvement and the later practical disappearance of the affection.

Dr. F. H. Koyle of Hornellsville, N. Y., gave a brief report of a case of tic-douloureux. The patient had an early history of unilateral hydrorrhea, this changing from side to side. An exostosis protruded into the right nostril and the right antrum was dark on transillumination. The antrum was opened through the canine fossa, but no cause for the neuralgia was found. Ocular origin was then inferred and the patient found to have astigmatism and heterophoria. These defects were corrected and the neuralgic attacks decreased, entirely disappearing in six months. The case was reported as one due to reflex action from ciliary ganglia irritation.

CHICAGO.

Northwestern University.—The trustees of this institution have decided to continue the medical schools for men and women as separate institutions.

Alumnæ of Woman's Medical School.—The Alumnæ Association of the Northwestern University Woman's Medical School recently held its twentieth annual meeting, at which action was taken towards the establishment of two memorial fellowships, one for the Chair of Physiology in memory of the late Dr. F. A. Wadsworth, who was Professor of this Chair at the time of his death, and the other for advanced work in the Chair of Gynecology, to be known as the Dyas Memorial Fellowship. The following officers were elected: President, Dr. Marion Kelly Bowles, Joliet, Ill.; first vice-president, Dr. Hezediah Crabtree, Chicago; second vice-president, Dr. Anna White Sage, Chicago; secretary, Dr. Eliza H. Root, Chicago, and treasurer, Dr. Caroline C. Hollister, Chicago.

Association of Visiting Nurses.—This Association cared for 542 patients during the month of May. The nurses made 2510 visits. The work of the Association, it is said, covers a larger ground than any similar organization in the country. The emergency staff of untrained women gives care to hundreds of persons unable to pay for the services of graduate nurses.

Will of Dr. Miller.—The will of the late Dr. Truman W. Miller was filed for probate a few days ago. Dr. Miller left an estate valued at $175,000.

Suicide of Dr. Locke.—Dr. Robert Locke, a graduate of Rush Medical College, and for a time associated with the late Dr. James H. Etheridge, shot himself through the heart in his room June 8th, at the Occidental Hotel, in San Francisco.

Samaritan Hospital.—This hospital was recently opened, and hereafter accident cases requiring immediate attention may be taken to this hospital instead of a long trip to the County Hospital, or other institution equally distant from the business center.

Physical Test for School-Teachers.—Dr. Julia Holmes Smith, Dr. Sarah Hackett Stevenson, and Dr. Florence Hunt have been notified of their appointments to examine applicants for admission to the normal school, and arrangements will be

made for physical tests. Dr. W. S. Christopher, who is the originator of the idea, believes that the great fault of the school system of to-day is that many of the teachers have not the physical strength to enable them to teach properly. The only way to remedy this defect is to provide the proper physical test before entering the normal school. If any of the applicants fail to pass the first examination, a second will be held. This plan is heartily approved, and it is believed that it will be of great value both to the teachers and to the pupils.

Metropolitan Medical College.—Post-Office Inspector Gould has received instructions from Washington to withhold all mail addressed to this fraudulent institution, or alleged "diploma mill," or to any of the men who have recently been arrested for connection with it.

Proceeds for Consumptive Hospital.—The officers of the Citizens' Committee for the erection of a hospital for the treatment of consumptives under the auspices of the Sisters of St. Elizabeth Hospital recently held a meeting and reported having received donations amounting to $19,064 to date.

Public Health Matters.—The death returns for the past week are the lowest recorded for a similar period since the week ended November 3, 1899. Consumption shows the greatest reduction in the number of deaths, there being but 35 during the week, as against 60 the week preceding and 50 the corresponding week of 1899. The unsatisfactory feature of the public health is the continued prevalence and high mortality of the contagious diseases of children—diphtheria, measles, scarlet fever, and whooping-cough. It is barely possible that the great decrease in the impure-water diseases since the opening of the drainage canal is merely a coincidence, but a comparison of the first five months of each of the ten years between 1890 and 1899, with the first five months of 1900, strongly indicates a relationship of cause and effect.

GENERAL.

Dentists at the International Congress.—Dentists not doctors in medicine will be enrolled as members of the Congress in the Section on Stomatology. This corresponds with the arrangement made by the American Medical Association.

Photography in Embryology.—A novel use of photography in embryological investigation has recently been made by Professor G. Farro. He has succeeded in registering the movements of the heart of an embryo chicken three days after its formation.

Malaria in the Philippines.—Malarial fever has been prevalent since April in parts of Cavite and Batangas Provinces, which are garrisoned by the Forty-sixth and Thirty-ninth Regiments. Thirty per cent. of the men of each regiment are on the sick-list. Of two battalions in Batangas Province, one has 150 sick and the other 190.

Nautical Hygiene.—Liverpool and London have for some time supported establishments that are specially devoted to promoting the health of seamen and to studying and treating the diseases to which mariners are peculiarly liable. Germany has now followed this excellent example and has established the Hamburg Institute for the study of nautical hygiene. Many of the old-time diseases, such as scurvy, night blindness, the so-called ship anemia, and chronic ailments of the digestive organs, if not yet quite extinct, have become rare. A series of new diseases has taken their place and are now having the attention of the medical faculty. In order to deal with these diseases such as malaria, beriberi, blackwater fever and other tropical disorders, special hospitals are needed at the large ports.

Bad Risks.—The Supreme Lodge of the Knights of Honor, in session at Buffalo on June 16th, voted to exclude Christian Scientists and Faith Curists from the order. Such persons are considered bad risks and the lodge does not care to insure them.

The Oxford University Degree.—Prof. James Mark Baldwin, Stuart Professor of Psychology in Princeton University, Prof. Charles E. Morton, of Harvard, the Rev. Dr. Morgan Dix, of Trinity Church, New York, and Prof. Charles F. Chandler, of Columbia University, will receive degrees from Oxford University this year. Professor Baldwin, who is now abroad, is engaged in editing the dictionary of psychology which is being published in England. He has also been honored by election to the French Institute of Sociology.

Obituary.—Dr. George M. Blakes died June 15th, in Bloomingburgh, N. Y., in his sixty-eighth year. He was graduated from the medical department of the University of New York. He served during the Civil War as a surgeon in the Fifty-sixth New York Volunteer Infantry. In politics he was a strong Democrat and was appointed examining surgeon from that district under both Cleveland administrations.—Dr. Burke Pillsbury, a prominent physician, died in Middletown, N. Y., June 16th, from the results of an operation. Dr. Pillsbury had devoted much attention to the study of tuberculosis, and was a member of the Tuberculosis Congress of Paris.

Hospitals Must Pay Duty.—Under a decision announced on June 13th, by the Board of Classification of the United States General Appraisers, hospitals are not entitled to import surgical instruments free of duty. Philosophical and scientific apparatus, utensils, instruments and preparations, which are imported not to sell but for an institution established "solely for religious, philosophical, educational, scientific or literary purposes" are admitted to free entry. The Mas-

sachusetts General Hospital had protested against the action of the Customs authorities at Boston in assessing duties on a lot of surgical instruments recently imported. The hospital has educational features, in that it trains nurses and gives clinical instruction to medical students. The Customs authorities decided, however, that these educational features are merely incidental to the main purposes of the hospital.

The Plague.—Last week we recorded the fact that the courts of San Francisco had failed to support the Board of Health in its effort to maintain a quarantine cordon about the Chinese quarters. The quarantine has therefore been abandoned and the Chinamen have made haste to get beyond the bounds of Chinatown and scatter themselves throughout the city and the State. The Marine Hospital Service thereupon attempted, under the provisions of the Interstate Commerce act, to establish quarantine at the State line and allow no Asiatic to pass beyond the limits of the State, without a certificate of health. This order however was promptly rescinded. The whole matter has reduced itself to the quarantine of individual cases. As there has been no occasion during the week to apply this precaution, excitement is gradually subsiding. Advices by steamer, Vancouver, B. C., June 15th, say that the plague is steadily increasing in Australasia. Many cases are reported in the colony of Victoria, which started in the slums of Melbourne. In Sydney there continue to be from four to six new cases daily and the percentage of deaths is high. In the city of Sydney there have been 239 cases to May 21st, eighty-two of which died. In Victoria there have been some 100 cases, and in Queensland fifty-eight.

The Australian correspondent of the *Lancet* writes: It is stated that the expenditure incurred by the Government in dealing with the plague amounts to approximately £30,000 a month. The work of prevention and extermination consists in quarantining areas in the city wherever cases occur and then employing the quarantined laborers in clearing out the filth that has been accumulating in them for years. The dwellings of "contacts" are thoroughly disinfected, mostly by the "formalin" process, and all persons in any way associated with plague cases are detained in quarantine for five days. The Government distributes free a special rat poison to all householders and sends round men to remove dead rats from premises free of charge. Many houses have been condemned and pulled down. A capitation reward is given for rats and an immense number have been destroyed. In connection with the mode of transmission of the disease Dr. Tidswell, the bacteriologists of the New South Wales Health Department has demonstrated the existence of plague bacilli in the alimentary canal of fleas taken from plague-affected rats. In all the colonies extermination of rats is being carried on most vigorously. In Victoria steps are also taken to prevent the introduction of rats from other ports in vessels. Every vessel must be kept four feet away from the wharf and all pipes, ports, and scuttles closed. All gangways and ropes, etc., by which rats might get ashore are to be kept in a sticky condition with tar and a constant supervision maintained by special watchmen. A special staff is employed in inspecting and seeing that regulations are carried out. Inoculations with Haffkine's serum are being freely employed.

At Port Said the condition remains unchanged, while at Juddah and along the Turco-Persian frontier the plague continues to spread.

CORRESPONDENCE.

THE PATHOLOGICAL INSTITUTE.

To the Editor of the MEDICAL NEWS:

DEAR DOCTOR:—In view of the great danger threatening the State Pathological Institute, I cannot refrain from adding a few words to the discussion which has been called forth. It is strange that this opposition to the work of the Institute should apparently have arisen in the house of its friends. A former Commission established the Institute on broad lines, and the results during its comparatively brief existence have been so important and substantial that psychiatrists and neurologists abroad and in this country have hastened to its support, when it was seen that its usefulness was to be curtailed. The work of the Institute has been accomplished despite the great difficulties always present in the investigation of mental phenomena owing to the intrinsic difficulties of the subject itself and to the fact that almost entirely new roads had in this instance to be opened. The signed protests presented in your last issue afford a remarkable testimony to the high estimation in which it is held. A strange condition is it, indeed, when we see the Commission in Lunacy trying to destroy its own child. The Committee appointed by the Commission in Lunacy to investigate the Institute have made a very inadequate report of its workings. From what I can learn little time was spent there, and the opinion of the Committee coincides with that previously expressed by the Commission too completely to be of value.

Some of the points made by it, however, have been refuted by the report of the work already done by the Institute. One point only I need here to refer to, that is the instruction of the staff of the various State Hospitals in the best methods of pathological research. This has been done in many instances and the Institute is always ready to receive such men for instruction whenever they can be spared from their duties. I have personally looked into the work of the Institute and know that not only has a large amount of pathological work been done but investigation from the clinical side has been always going on. Epilepsy, hysteria, amnesia, subconscious phenomena of abnormal life have been studied, the

most advanced modern methods being followed. The choice of the material to be used must be left to the Director; he must be free to take it from the hospitals or from other sources. It is in this way only that some intelligent method of treatment for this class of cases can finally be evolved.

In conclusion allow me to emphasize my great regret that the usefulness of this Institute is now threatened by probable changes which, if carried out, will take away from it its opportunities for scientific investigation.

Edward D. Fisher, M.D.

No. 42 West 45th St., New York.
June 19, 1900.

OPINIONS OF REPRESENTATIVE MEDICAL MEN REGARDING THE PATHOLOGICAL INSTITUTE.

To the Editor of the Medical News:

Dear Sir:—As a further indication of the estimate in which the value of the work of the Pathological Institute along its present lines is held, both at home and abroad, I send you for publication a few letters selected from many that have been received, some written independently and some accompanying the protests against the present steps that are being taken toward the crippling and subversion of our scientific work in psychiatry.

Ira Van Gieson.

1 Madison Avenue, New York,
June 19, 1900.

Dear Dr. Van Gieson:—I am heartily in accord with the purposes and work of the Pathological Institute and of the broad lines on which you have proposed to carry it on. I should consider it a great misfortune to have its work interfered with.

Charles L. Dana.

New York, May 15, 1900.

Dear Dr. Van Gieson:—Please enter my name on one or both of the protests against the proposed destruction of your Institute. Your Institute has been held up and looked up to as an example of what should be done in every State, and, hence, I feel that any crippling of its efficiency is nothing more than a base assassination of scientific research in medicine.

F. G. Novy.

University of Michigan, May 19, 1900.

[To Dr. Sidis.]

Sir:—I beg to advise you that I understand but imperfectly the question which you have addressed to me; but if it concerns the suppression of the Pathological Institute I profoundly deplore this suppression, having appreciated by the perusal of your "Psychology of Suggestion" the part which you have taken in it.

Th. Ribot,
Editor of *La Revue Philosophique.*

Paris, May 22, 1900.
[Translated.]

My Dear Dr. Van Gieson:—I gladly sign the accompanying protest and only wish that I could be of the least influence in helping you. Your scheme is admirable and you have gathered around you a band of singularly brilliant workers.

I often find myself working along lines that are not commonplace and recognize how if one does this, one must be prepared to find the work not immediately appreciated. Do not, however, be discouraged, for this "Grenzgebiet" work is that which is assuredly the most inspiriting and the most valuable for our profession. I wish you all success.

J. George Adami.

McGill Medical Faculty, Montreal,
May 15, 1900.

Dear Dr. Van Gieson:—Your letter of the 17th is at hand. I have taken much interest in the present controversy of the New York State Commission, in fact am quite familiar with the plan of those who are interrupting the good work of the Pathological Institute, and regret very much that the value of such scientific investigation is not universally recognized, and hope that you will be successful in your efforts. Inclosed please find protest, which I have signed.

Theo. Klingmann.

Pathologist to the Michigan State Asylums for the Insane,
Ann Arbor, Mich., May 19, 1900.

Dear Dr. Van Gieson:—In looking over the Archives of Neurology I am much surprised by the interest and novelty of the studies. If anything should happen to your Laboratory I should regard it as the greatest misfortune that neurologists could encounter in this country. I do not know whether I am wise to say it, but I think the progress in the treatment of insanity has nearly stopped. In this respect there has been little or no gain during the last few years. Moreover, I am equally sure that asylum methods do not give the individual care which appears to me essential in the treatment of insanity.

I do not know whether this letter is one that you can use or not; my object in writing it is simply to state my individual belief in the value of the work done by yourself and your assistants.

S. Weir Mitchell.

Philadelphia, May 10, 1900.

Dear Dr. Van Gieson:—I enclose a protest against the crippling and destruction of the work of the Pathological Institute of the New York State Institution in Lunacy with my signature attached. I signed the paper with much pleasure and only hope it may prove of some slight use to you. I am surprised and intensely disappointed to think that there could be any move on the part of any members of our profession towards hampering the work of an institution which has done the amount of careful, earnest, scientific work which I believe your Institute has done. I earnestly hope this work may not be interfered with.

Jo. H. Linsley.

Vermont State Board of Health, May 19, 1900.

DEAR DR. VAN GIESON:—I think that I fully appreciate the value of the work that you have been doing at the Pathological Institute, both in its relation to pure science and to psychiatry in particular. Your plans are not only broad and comprehensive in their scope, but are well devised to attain ultimately such results as are desired by all who are interested in psychiatry and who wish to see it placed on solid foundations.

Just such work as you have been doing must be done; the several rays from the various sciences must be gathered and concentrated upon the problems of psychiatry before any substantial progress can be made in their solution.

It will be an everlasting credit to the State of New York that it has fostered the inception of this most important work, but the shame will be even greater if it should fail to recognize the necessity for its maintenance as a civil responsibility.

WM. J. HERDMAN.

University of Michigan, May 19, 1900.

[To Governor Roosevelt from Prof. James of Harvard.]

DEAR GOVERNOR:—I am taking the liberty of meddling in New York State affairs by sending you a line touching my humble opinion of the importance of letting the Pathological Institute develop on its present lines peacefully for a number of years before it is judged.

I am told that Dr. Van Gieson meets with severe criticism in the profession and you will probably hear the work there called "cranky" by men of respectable judgment. So far as the *lunacy* work goes—that is the only part with which I am acquainted—I think it would be a real *calamity* to have any obstacles put in its path. Convincing results will doubtless come as fruits of the truly psychological observations that the Institute is now having made, if time is only allowed. It is probable that eventually the Institute may become quite *glorious* from what it is now doing. I know enough of the medical mind to have little esteem for its opinions when they are conservaative. I really believe that Van Gieson deserves support; and hope that you will not listen too confidingly to attacks on his methods.

WILLIAM JAMES.

Cambridge, Mass., February 11, 1899.

OUR LONDON LETTER.

[From Our Special Correspondent.]

LONDON, June 14, 1900.

THE POLYCLINIC—MR. JONATHAN HUTCHINSON ON THE "STORY OF ROBBEN ISLAND"—LEPROSY IN SOUTH AFRICA—THE SEGREGATION OF LEPERS A CRUEL INJUSTICE—THE ANTITUBERCULOSIS MOVEMENT—ESTABLISHMENT OF A SANATORIUM AT DUNDEE—MEETING AT LIVERPOOL—DEATH FROM A BEE-STING—LEAD-POISONING AND EMPLOYERS' LIABILITY.

A CONVERSAZIONE has been given at the Polyclinic in connection with the annual dinner which will take place on Thursday. Lord Strathcona and Mount-Royal, formerly High Commissioner for Canada, and the President, Vice-Presidents and Officers of the College gave a reception. The event of the afternoon was a lecture by Mr. Jonathan Hutchinson on "The Story of Robben Island." Robben Island is a small island situated near Cape Town where lepers are compulsorily sent from South Africa with the idea of preventing the spread of the disease. Mr. Hutchinson, who strenuously advocates that leprosy is not a contagious disease, said that the leper-establishment there is to be regarded as a prison rather than a hospital. Some of the medical officers carried revolvers and, when this fact was commented on at an inquiry, one of them answered that he did not regard the place as a hospital. The plea that these lepers are confined to prevent the spread of the disease is insincere for there are 14 healthy children in the women's wards. When Dr. Impey was taxed with this fact he simply replied that if he separated the children from their mothers he would have so many demons left on his hands. He had also stated that he had never known any official, doctor, policeman, warder, or nurse to acquire leprosy on the island. If, then, leprosy is, as he maintains, a non-contagious disease, it is cruel injustice to keep 550 poor creatures in a state of confinement on a desolate island. Husbands have been torn from wives and mothers from their children in consequence of the erroneous view which prevails on the subject. Mr. Hutchinson pointed out how necessary it is that there should be a well-informed public on this as well as on other subjects, such as vaccination, hydrophobia, etc. Their cooperation is required in order that the full benefits of medical science should be reaped. If leprosy is a contagious disease, why did it totally disappear from the British Islands and from inland Europe? In consequence of the advance of civilization which brought with it improved habits of diet and not from segregation. Even now leprosy in its early stages is a disease difficult of diagnosis; therefore, segregation in the old "leper-houses" must have been very incomplete. Moreover, into these houses patients with other diseases were admitted. In one case a house was half a blind asylum and half a leper-house. Segregation has failed in the Sandwich Islands. Robben Island is a disgrace to the nineteenth century. The one cry of the poor creatures sent there is, "I want to go home!" Of it there might be said "All hope abandon ye who enter here." Many die there of a broken heart. The true cause of leprosy is the eating of uncooked salted fish which probably contained the bacillus. The fact that it is dotted here and there all over South Africa, a few cases occurring here and a few there, show that it is not contagious. No such thing as a violent outbreak has ever been recorded. There are no records of leprosy in South Africa before the Dutch introduced a number of Malay slaves to found a factory for drying fish. Leprosy is prevalent amongst the Hottentots who eat fish, but

does not affect the various Kaffir tribes, Zulus, Bantos and Basutos who do not. Mr. Hutchinson then pointed out the great value to medical science of the Polyclinic. In this institution standing committees have been appointed to investigate leprosy and many other questions, such as tuberculosis, geography of disease, etc. The Polyclinic is not a mere British institution, but exists for the benefit of the whole Empire. Its object is to improve medical knowledge in general.

The antituberculosis movement still proceeds apace. Plans for a sanatorium to be erected at a cost of $50,000 have been submitted to a committee of the Dundee Town Council. The building will be admirably adapted to its uses. The main blocks will have a frontage of 200 feet and will accommodate 18 males and 16 females. Each room for the patients will face south with an oriel window giving access to the terrace and gardens. The corridors will extend from end to end of the building and will be fitted with French windows reaching close to the floor, to admit as much fresh air as possible. At Liverpool a large and influential meeting convened by the Lord Mayor has been held to establish a branch of the National Association for the Prevention of Consumption. Lord Derby presided. The Lord Mayor said that consumption causes 60,000 deaths annually in Great Britain and that a quarter of a million of persons are now suffering from the various forms of tuberculosis. Liverpool loses 2000 persons yearly from consumption, the majority of whom are in the prime of life. The disease has now been shown to be both preventable and curable. Mr. Malcolm Morris, to whom is due the credit of initiating this great movement, said that he never dreamed that this subject would catch on so remarkably with so many classes. The gathering at Marlborough House presided over by the Prince of Wales made the subject fashionable—a very important consideration Mr. Morris said. He had come to Liverpool to preach the doctrine of the open window by day and by night. How many in that room slept last night with their windows open? Is there any fetid air to be compared with the air of the rich consumptive's bedroom twenty years ago? Even at Glasgow 32 per cent. of the consumptives have been cured and 44 per cent. partially cured, while in another place 65 per cent. have been able to return to work.

A case of death from a bee-sting has occurred at Saint Arvans, a village near Chepstow. A young woman, Miss Greenway, accompanied her uncle, Mr. George Greenway, a bee specialist, to the rectory, where she was stung by a bee and died within a few minutes. At the inquest the medical evidence attributed the death to syncope produced by the poison of the bee-sting. It was stated that Miss Greenway had on several previous occasions fainted after being stung by bees. Some time ago, in December, 1898, a case was published in the *Medical Review* of death from a wasp-sting: A strong healthy girl, aged twenty-four years, was stung on the hand by a wasp. A few minutes afterward her face became very red. She complained of numbness all over and of loss of sight. She then fainted. Curiously in this, as in the preceding case, similar symptoms had occurred on a previous occasion when she was stung. Her face turned suddenly pallid and she expired in about twenty-five minutes. These two cases go to show that the very rare fatal results of bee- or wasp-stings are due to idiosyncrasy on the part of the patients.

An action brought by a workman to recover damages from his employers in consequence of lead-poisoning shows the stringent precautions taken by the Government to protect workmen from injury in their occupations. The defendants are large manufacturers of gas-fitting and similar articles in Manchester. The plaintiff worked in a room where fittings were put together and white lead used. After the fittings were put together he had to suck them with his mouth in order to ascertain whether they were air-tight. The proper course would have been to have used a pump, but one was not provided. The atmosphere of the room was vitiated by a lead-burning machine. While working he was taken ill and fainted. He had to give up work and learned from his medical attendant that he was suffering from lead-poisoning. Judgment was given for the plaintiff with £45 damages and costs.

SOCIETY PROCEEDINGS.

AMERICAN MEDICAL ASSOCIATION.

Fifty-first Annual Meeting, Held at Atlantic City, N. J., June 5-8, 1900.

Section on Surgery.

(Continued from page 939.)

Third Day—June 7th.

Hernia in Children.—The results of operative treatment in children are better than in adults, said Dr. A. J. Ochsner of Chicago, and if the same indications can be established early operation should be encouraged, otherwise non-operative management, because in the majority of cases it cures absolutely. Statistics show inguinal hernia occurs 300 times to 1 femoral in the child and the London Truss Company make the ratio 10 times greater. All large umbilical and ventral hernias in children are fatal. The chief predisposing causes are the anatomy of the formation and descent of the testes, unduly long mesentery, congenital or acquired by intestinal distention, in 25 per cent. of all cases inherited local and systemic weakness, poor nutrition and general softness and flabbiness of the muscle-tissues. The exciting factors are intra-abdominal pressure due to intestinal disturbance, flatulence, distention, constipation, urinary obstruction in phimosis, and obstinate cough or violent cry-

ing. Often the mother notices the protrusion and fearing the effects of crying feeds the baby whenever it whimpers, brings on thus indigestion, distention, constipation and, hence, really increases the lesion. Therefore, we find these conditions so often among the ignorant and poor who neglect advice. Many hernias heal before the child's sixth year, when statistics show 1 to exist in 21 patients; from that to the thirteenth year there is still more spontaneously cure, so that the ratio is 1 in 77; of these still more tend to disappear before adult life. Heredity of weaknesses through intermarriage among the Jews counterbalances the advantages of circumcision and accounts for the great frequency of hernia among them. Coley has shown that only 5 per cent. of all adult cases date their history back to infancy and childhood. The great element of the treatment is to keep the sac empty and to remove the cause, especially intestinal disorder, constipation, and phimosis. The spreading of the pelvis in growth tends to make the inguinal canal more and more oblique, to close the internal ring more completely, and to shorten the mesentery by converting some of its redundancy into parietal serosa. If the child be put into a bed with elevated foot, all causes kept corrected and the sac empty, many cases promptly begin their recovery. Others require a truss night and day to flatten and close the canal. The operative cases should be confined solely to (1) patients over 4 years old; (2) reducible recurrent hydrocele; (3) irreducible hernia; (4) incarcerated hernia; (5) strangulated hernia. The technic should stop with the ablation of the sac and closing of the peritoneum and internal ring. Repair of the canal is to endanger the health of the testis by doing too much; therefore, as a rule, the restoration of this part had best be left to Nature in children.

Ventral Hernia.—Dr. M. M. Johnson of Hartford, Conn., reviewed the causes, as follows: Deficient aponeurotic development, imperfect closure of surgical wounds, use of drains, undue damage in long incisions, stitch-abscesses and other wound infection, all healing by granulation, division of motor nerves and atrophy of the muscles supplied, lowered vitality in such systemic disease as tuberculosis, syphilis, and fatty degeneration due to the menopause. Ventral hernia occurs in 10 per cent. of all abdominal sections, whether median or extramedian. His method of treatment is, after separating the aponeuroses as far as possible, to pass silver wire relaxing sutures about one inch apart, as in the old-style "quilt sutures." The layers are then approximated by continuous animal sutures, each by itself, the skin closed and then the wires are tightened. After ten days attenuated wires are removed and the others in five days more. The patients remain in bed three weeks. His results have been good.

Male Inguinal Hernia.—All hernias, not inguinal, holds H. O. Marcy of Boston, are protrusions through relatively large holes and essentially short direct canals, but inguinal hernia has a larger indirect oblique avenue of escape. Opposite the internal ring there is normally no *processus infundibuliformis peritonei*, unless the cord be drawn down. When present this is an anatomical defect and contributes to the formation of a hernia by keeping the internal ring more or less patent. Lack of development is the great cause predisposing to hernia, because in the perfect inguinal canal the pressure from within acts laterally, just as by the oblique course of the ureters into the bladder, injury by back-set of the urine to the kidneys is prevented by the lateral compression upon the ureters by the vesical distention. The inguinal canal and the vesical ureteral implantation are the only two examples of this mechanically advantageous arrangement in man. Given the anatomic defects and any of the usual causes, slowly and gradually the viscus appears beyond the external ring and reaches the scrotal extremity. In operating he considers the following points as necessary for cure: (1) A skin-wound large enough to expose well all the factors and to enable free separation and retraction of the cord. (2) The complete emptying and ablation of the sac. (3) The closure of the proximal end of the neck short and within the general peritoneal cavity. (4) The use of sutures for this step rather than ligature which may engage some aberrant vessel and cause gangrene and death, as proved by an autopsy cited. (5) Careful reconstruction of the inguinal canal with reference to its normal obliquity. (6) The employment of buried continuous animal sutures, one for each of the two layers, avoiding the many knots of interrupted sutures and dangers of buried non-absorbable material. (7) The closure of the wound without drain. (8) The covering of it with an iodoform-collodion seal, and (9) no other dressing. The subcutaneous transplantation of the cord beyond the internal ring he condemns, because it substitutes a short direct hole by incision for the natural long oblique canal. The more complicated procedures of transplanting the pyramidalis and of interweaving the various structures have no advantages over the typical operation. The strong eversion of Poupart's ligament and the suturing of the conjoined tendon to its abdominal and posterior aspects are highly efficient details of the general procedure.

Dr. W. B. De Garmo of New York opened the discussion and said that the greatest single predisposer to hernia is any deviation from the normal anatomy of the tunica vaginalis testis and might at any possible period of life, very early, very late, or in middle life, suddenly manifest itself as such. Dr. Marcy had years ago maintained this action and described it fully. Dr. De Garmo repeated with renewed force his agreement with Dr. Marcy that the Bassini operation, with the details of special care enumerated by him, is the sole means of radical cure. As to children, he said 95 per cent. of all cases are spontaneously cured by the fifth year, and that

under ordinary conditions this would be the earliest period for operating. Confinement in bed usually works disadvantage to the patient's system and is to be set aside in the presence of a good truss which enables playing and normal life. The greatest point in ventral hernia is to separate and unite the layers, each to each, and to support the repair-work by some type of non-absorbable relaxation sutures, preferably silkworm gut.

One very active cause of hernia, argued Dr. Ferguson of Chicago, had not been mentioned, namely, the absence or deficiency of attachment of the internal oblique to Poupart's ligament. Only the muscle-structures are the active, all the others (peritoneum, fascia, ligaments and aponeuroses) in the anatomy of hernia are really passive elements. In the normal male the internal oblique takes origin from the outer third; in the normal female, from the outer half of Poupart's ligament. The fact gives her a better internal ring and, with the smaller contents of the canal, is the reason why she has fewer inguinal hernias. In 90 per cent. of all inguinal hernias this attachment will be found deficient and in 5 per cent. not to extend down Poupart's ligament at all beyond the anterior superior spine. To his mind, radical operations are of two kinds, (1) those which restore the normal conditions with more or less normal tissues; (2) those which are really plastic with tissues thinned, weakened and damaged by improper truss-pressure.

Dr. Mayo of Rochester, Minn., considers six weeks of bed-treatment highly advantageous for children. To one point of the Bassini operation he always gave attention, namely, the creation of a deep internal lower scar and an outer superficial higher scar. This is done by pulling down the lower aponeurotic flap with Poupart's ligament. To the posterior and abdominal surface of this, the deep structures are carefully secured, giving the deep internal lower line of scar. The aponeurosis is then sutured in the usual way, after the lower flap of it has been replaced, thus giving the superficial external upper scar. This difference in scar levels tends to enhance the operation very much.

Dr. Ochsner said that his bed-treatment works practically better than it would theoretically appear, because it substitutes good diet, healthy surroundings, absence of cause, emptiness of the sac, for the opposite of all, many of which can not be reached so well by truss-wearing and leaving the child at home.

Dr. Marcy went over the anatomy of hernia and proved the need of restoring the obliquity of the canal. He said early operations in children are by no means to be dreaded, but often are better than truss-wearing. Ventral hernia has occurred but once in his last thousand laparotomies of clean type; hence he feels that layer-by-layer suture is of prophylactic importance.

Dr. Johnson said when a hernia occurs through a granulation wound it is impossible to separate the layers, but that relaxation sutures make better the chances of good results.

Drainage of Lung Cavities.—Two cases were cited by Dr. W. L. Mills of Los Angeles, Cal., to show that this procedure may succeed. In rabbits attacks upon the lungs are well borne—so well that he determined to make an attempt to drain lung-abscesses in man. After six years he finally found a patient willing to undergo the hazard. The history had been one of repeated pleurisy, probably tubercular, emaciation and failure. Physical examination showed a left apical cavity, much consolidation, tubercle bacilli and elastic fibers in the sputa. Night-sweats and vomiting and coughing of pus had occurred. Good diet, rest, creosote and healthy surroundings so improved the condition that he refused interference and went home. In a short time he came back in a relapse, very septic, and ready to accept any relief. The inflammation had extended forward, where at the sixth rib, in the anterior axillary line, the abscess appeared about to point. Under ether attack was begun at this point, but no abscess or pleurisy was found. Collapse threatened and a drain-tube was hurriedly inserted. On the ninth day a sudden copious discharge of pus appeared through the tube and more was expectorated. Irrigation with bichloride solution, 1-4000, finally checked this in sixteen months. The patient has gained 75 pounds and is able to do hard manual labor.

The second case had a similar experience, nearly dying on the table, but after a few days evacuated a gangrenous abscess in both directions, bronchi and wound. The progress of his other tubercular processes will finally kill him, although sepsis from the pus has disappeared. Neither was an instance of empyema, because the pleura were normal. The effect of bichloride of mercury in the first man suggests the possible value of it in all tuberculosis. The dry climate of California was no doubt an aid in each of these patients.

Dr. Murphy of Chicago discussed the question of lung-abscess and said those with adhesions can be freely evacuated externally, with the knife better than the cautery. Such as have excited no fixation of the viscus to the parieties may be evacuated externally in two sittings, the first of these concerned with creating the adhesions. A safer method is to plunge a needle into the pleural cavity; allow 120 to 180 c.c. of air to enter by respiratory suction; collapse and compress the lung, rupturing the abscess into the bronchi and so alleviating the septic condition.

Skiagraphic Errors.—Dr. Carl Beck of New York City claims that every surgeon should be aware that lesions can be located and defined only views in several directions. Fractures often fail to appear in one but are always clear in another view. The examination of both the normal and diseased sides is needed to bring out anatomical confirmations and peculiarities, such as the occurrence of the *os intermedium pedis*. The effect of epithelial lines simulating fracture, of the cartilaginous bones of the young carpus simulating absence of development, the appearances of

new and old fracture lines, etc., all should be matters of common knowledge.

Skiagraphy in Urinary Calculi.—All the known modern methods for diagnosis of calculi, pleaded Dr. C. L. Leonard of Philadelphia, are complementary of each other and combine into a whole mass of evidence, although alone each has its limitations: Urinary analysis of collective and unilateral secretion; centrifuge; segregator; ureteral catheterization; cystoscopy; bacterial examination; determination of the functional activity of each organ; evacuator, radioscopy, etc. The best combination is, with the necessary laboratory examination of specimens, radioscopy, ureteral catheterization and sounding with the wax-covered catheters in Kelly's method, segregation with the Harris apparatus, and study of the pain and other symptoms. The wax-tipped catheter may fail to touch a stone in the renal substance itself, but is of great value when the stone is of fair size and is in the pelvis or course of the ureter. Its greatest sphere is to indicate comparative functional activity of the two organs. With a history of colic the evacuator may demonstrate a calculus in the bladder, but can not show whence it came. In most of these procedures the operation must at once follow the examination. His experience with the skiagraph covers 20 cases, 4 ureteral, 3 multiple, 4 bilateral and the balance single. This method has the following advantages under perfect technic and proper reading of the negatives: (1) Mathematically and mechanically accurate results; (2) absolutely trustworthy negative and positive data alike; (3) detection of all stones of whatever chemical formation and age and number, none left out; (4) examination of the whole tract, kidneys, ureters and bladder; (5) limitation of the nephrotomy to the exact site of each stone; (6) determination in high probability which side should be attacked first in bilateral disease; (7) entire prevention of the sequelæ and complications of unduly free exploration in cases doubtful under the older means of diagnosis; (8) fixed limitation of exploration to the perirenal regions, instead of including the kidney too. Failures are due to some error in handling the apparatus or in reading the negative, except in unduly fatty and very muscular people when it often becomes of questionable value.

Injuries of the Ureter.—This topic of accidents to the ureters during intra-abdominal operations was tersely handled by Dr. B. B. Davis of Omaha, Neb. In his reported case in removing a broad ligament growth the ureter had been divided and a short length of it resected. Its repair was made in about five minutes, as follows: A catgut suture mounted by a straight needle at each end was fixed in the proximal end from within outward, so that the needles emerged at parallel points a quarter of an inch from the division. Through the end of the distal stump, slit down about one centimeter for space and held open with small artery forceps, the needles were again passed from within outward through parallel points, traction on the suture and coaxing invaginated the upper into the lower end. The suture was then tied and a small drain inserted to the point of division. Uneventful recovery followed. He then compared the various methods in use for such accidents: (1) A permanent urinary surface fistula and its drag on the patient and community, by suturing the upper end into the skin and tying off the lower; (2) the cruder, often fatal, way of simple ligation, leaving the patient to die of anuria, first by obstruction, then by reflex action on the opposite side; (3) the sacrifice of the kidney with frequent similar results or death from shock; (4) implantation of the ureter into the rectum, sigmoid, colon or small intestine; (5) into the bladder directly; (6) end-in-end; (7) end-to-end; (8) lateral uretero-ureteral anastomosis. The conclusions were that the anastomoses provide, for the escape of urine through its natural channels, for no loss of function, for the least possible damage to the urinary system. The cicatricial contraction is very slight, and of no practical importance. The operation is readily done. The upper keeps the lower end open in the end-in-end method. If the loss of ureteral substance prevents uretero-ureteral junction, the second choice lies with the implantation into the bladder, and the third into the rectum, sigmoid or colon. In this last procedure ascending infection of the kidney is always to be dreaded.

In the discussion Dr. Kelly of Baltimore said that his wax-coated catheters have limitations. In one case, with diagnosis of left disease, he obtained pus but no scratches; on the right side, which gave no symptoms, he found scratches but no pus. The skiagraph showed stones on each side. The left and then the right were successfully treated. In skilful hands, with careful interpretation of plates taken from several directions he regards the skiagraph as absolutely diagnostic. As to ureteral anastomosis he prefers the end-to-end plan, using therefor his anastomosis guide, similar to a double-end cartridge, which, introduced into the ends, permits ready placing of the sutures which are then carefully tied. The same device is successful in joining the ureter to the bladder. He reported a case in which so much of the ureter had been lost that to avoid tension he shelled the bladder out of its bed, sutured it to the psoas muscle, and then did the anastomosis. The result was admirable.

Dr. Bevan of Chicago reported an X-ray diagnosis of three calculi, two in the pelvis of the kidney and one in its substance. This last would probably have been overlooked had not the radiograph compelled most careful search and indicated its site.

Dr. Bovée, Washington, D. C., enumerated his choice of ureteral operations, in order as follows: (1) End-to-end, transverse or oblique; (2) end-in-end; (3) end-into the side; (4) side-to-side; (5) implantation into the bladder; (6) into the gastro-enteric tract. Of the last there had been

80 successful cases, without ascending infection. He knew of one case of stenosis following anastomosis and that was due to tuberculosis.

Dr. Goodhue of Dayton, O., praised the radiograph diagnosis and reported an experience antedating its adoption. Pain in one side caused exposure and removal of a slightly-diseased kidney. At the autopsy soon after, the opposite kidney and its pelvis were found packed full of stones and pus. He also mentioned a successful case of end-into-side uretero-ureteral junction.

Dr. Winslow of Baltimore showed that the calices may be very late in joining to form the pelvis, remaining as so many separate tubes. A stone impacted in one would easily escape the wax-coated catheter, but not the X-ray.

Dr. Carl Beck of New York said that the negative radiographic diagnosis is untrustworthy, as many renal-like biliary calculi give no shadow.

Dr. McArthur of Chicago said that in his experiments he had laid uric-acid stones upon the plate and obtained no record, hence he regards the X-ray as open to grave doubt.

Dr. Summers of Nebraska described a case of double ureters he had encountered and emphasized the ready versatility the surgeon must possess.

Dr. Carpenter of San Francisco removed two inches of a ureter accidentally and successfully implanted the stump into the bladder through a long cut. The ureter entered the bladder-wall at the upper limit and emerged into the cavity of the viscus through the lower limit of the wound. Thus, the normally oblique entrance was imitated. He showed a device like the Murphy-button for urethral union and proposed to attach a thread to it to avoid its retention and obstruction. He acknowledged the great danger of phosphatic deposits upon it and thus occlusion of its lumen before the union is perfect.

In summing up Dr. Leonard replied to inquiries for the details of his technic by referring to his paper on this point in *The Annals of Surgery*, February, 1900. He asserted that all concretions *except cholesterin* are positively diagnosticated by the skiagraph. A tube the resistance of which equals a two-inch or three-inch spark through the air is too strong, one of the self-regulating tubes maintaining an even resistance of about a one-and-a-half-inch spark in the air is the proper thing to employ. Of his 20 cases he failed in only one, because his plate did not take in the whole region. The stone was in the top of the kidney and his plate contained only the lower half. The size and position of the plate are also important therefore.

Dr. Davis' final statements were that since ureteral damage usually occurs in long operations, rapidity is the great aim: hence, his preference for end-in-end over the more troublesome end-to-end style. Buttons in the ureter would almost surely clog before union could occur.

Exstrophy of the Bladder.—The features of the treatment of the patient, who was shown by Dr. A. M. Vance of Louisville, Ky., are that two large V-shaped incisions, one in each side with their angle embracing the limits of the exposed bladder, were made. The flaps thus created were boldly loosened and drawn to the median line and secured. In this way the mucous membrane on their deep surfaces turned in to form the anterior bladder-wall. Seven operations extending over nearly three years were required before plastic repair of the complete epispadias and bladder was finished. The patient has a penis which will erect four inches, but must wear a rubber urinal. His mental and physical states are much better. The bladder will hold about four ounces.

Dr. Willard of Philadelphia began the discussion by saying that even repeated operations fail, especially if skin is turned into the bladder, because urinary salts persist in depositing upon the hairs of the skin. He recommends securing a reservoir for the urine with good control in sphincter ani by implanting the ureters into the rectum, or, better, into the sigmoid or colon. If the trigonum be carried into the operation, the natural valves will prevent an ascending infection to a very large degree.

Dr. Kelly of Baltimore has failed to find that a loosening of the sacro-iliac joint affords sufficient relief of tension for perfect result. He thinks that shelling the imperfect bladder out of its bed will give ample freedom for plastic work without tension.

Dr. Hertzel of Chicago stated that in animals direct anastomosis between the bladder and rectum rarely gives cystitis and never infection of the kidneys. The natural valves seemed to afford protection.

Dr. Eastman of Indianapolis once did a left nephro-ureterectomy and sutured the right ureter directly to the urethra with fair results.

Dr. Connell of Chicago said that literature gives two classes of operation for this trouble, palliative without control and radical with control through the sphincter ani. This latter class includes, (1) direct transverse section of the canals and anastomosis into some part of the intestines; (2) direct vesicorectal anastomosis; (3) implantation of the trigonum; (4) oblique implantation into the gut, imitating the oblique entrance of the ureters into the bladder; (5) creation of a permanent artificial anus, with implantation into the rectum converted into a bladder; (6) resection of a portion of the small gut, formation of bladder out of it and implantation.

Dr. Summers of Omaha has seen four cases. In one, a female, he successfully carried the ureters into the vagina while restoring the bladder.

Dr. Vance in closing said the obstacles were sepsis from the urine and infection of the suture lines, erections even in small boys, and the relief of tension.

Urethral Asepsis.—Urinary diluents and disinfectants, stated Dr. F. C. Valentine of New York, are not to be compared in reliability with frequent irrigations in urethritis and cystitis. Piston syringes are often out of order and can not be so well

regulated as to pressure as the fountain. For the past seven years he has irrigated the urethra before and after any form of instrumentation and has had no cases of urethral fever. The irrigation seems to prevent it. He then showed a device consisting of a collapsible soft rubber reservoir, tube, cut-off, nozzle and shield which may be boiled and is suitable for office and home use. Its advantages are (1) adaptability to prostatic and septic cases; (2) perfect antisepsis and asepsis; (3) greater reliability than internal medication; (4) preference to the piston syringe; (5) avoidance of fever; (6) better asepsis than exists with the hands and instruments; (7) facility for use in the office; (8) in the home or during traveling when the doctor is away; (9) avoidance of danger in the catheters themselves.

Prostatic Hypertrophy.—Dr. Parker Syms of New York carefully described the importance of this disease from the standpoint of its frequency, complications, sequelæ, and pathology in acting as a dam to the urine, causing dribbling, residual urine, vesical dilatation and atony, chronic cystitis, finally, infection of one or both kidneys. Catheter-life is the end of these patients with recurrent subacute cystitis, then chronic, and, last, pyonephritis, unless the obstruction be removed by operation. He prefers prostatectomy to the prostatotomy of Bottini with which he had had little experience. The contraindications for enucleation are disease of the kidneys and arteriosclerosis. If attention be given to these the results would be better. The indications are to operate on generally sound patients as soon as catheter-life is inevitable. Perineal enucleation is the best, combined with a small suprapubic cystotomy, so that the gland can be pressed downward or the same accomplished by suprapubic pressure on the intact thin parieties. Still better is the insertion through the divided deep urethra and bladder, as in Alexander's operation, of a rubber bag devised and exhibited by himself. This should be filled with water and employed as a retractor to draw the gland down. In the presence of cystitis it is well to drain the bladder; in its absence it is better not to enter either the urethra or the bladder.

Opening the discussion, Dr. Thayer of Clifton Springs, N. Y., said that a simple fountain syringe with a shield had all the advantages of the costly Valentine device. Dr. Glenn of Alabama said that in fifteen years' experience he has never irrigated except in purulent urethritis and never has seen fever when clean instruments and sterile unguents are employed. Dr. Young of Baltimore uses the Bottini operation in simple cases. In median lobe hypertrophy he makes two cuts. After introducing the instrument he rotates it to one side, withdraws it until it engages and cuts. Then he repeats it on the opposite side. Suprapubic prostatectomy is also valuable. Dr. Chismore of San Francisco says over-irrigation damages. The prostatic field is well exposed by the dorsal position with the knees strongly flexed on the chest. Dr. Beck of New York not only irrigates the urethra freely, but also injects iodoform and glycerin after instrumentation. Dr. Robbins of Detroit said that urotropin alone is a good urinary antiseptic. Dr. Eastman of Indianapolis said that a piston syringe in the skilled hand is best and fulfils all the requirements of convenience, ready sterilization, and copious irrigation. Dr. Billett of Louisville, Ky., does a suprapubic prostatectomy with drainage by choice.

Dr. Guiteras of New York made the following points: Simple urethral irrigation is always good. Rapidity comes with practice. Never let the patient irrigate himself if he have a stricture or prostatic enlargement. Never let him use any but very bland solutions. A piston syringe may not work well; hence, a fountain is better. Always stop as soon as the patient says the bladder feels full, otherwise strain and hematuria result. Prostatic treatment is still in its infancy, choice lying between catheter-life and enucleation. Never operate if the kidneys and blood-vessels are diseased. Enucleate when the lateral lobes are enlarged. Do the Bottini operation when the middle lobe is moderately enlarged, the suprapubic if it is much increased in volume. Learn the value of rectal touch and instrumental examination of the urethra.

Dr. Valentine closed the discussion by saying that he had combined the cystoscope and Bottini incisor to avoid some of the objections the operation had of being done in the dark. He had no instrument to show.

Fourth Day—June 8th.

Tubercular Knee-Joint.—Dr. Wisner R. Townsend of New York emphasized the importance of both constitutional and local treatment. There is no specific for tuberculosis, but good diet, tonics, creosote, guaiacol, change of climate, and out-of-door life, will do much to aid the system in combating the disease. Locally rest, protection, correction of deformity, removal of the tuberculous foci and prevention and cure of complications are the indications. Protection and rest are usually obtained by some form of splint, preferably one like the Thomas used much at the Hospital for Ruptured and Crippled in New York City. With it observation of the progress of cure can be made. It is lighter than plaster of Paris and gives less irritation to the skin. The shoe of the sound side is built up so that in walking, which must be with crutches, no jar or function is allowed on the diseased joint. Any weight on that side is received entirely on the pelvis through the perineal ring so that the knee is not disturbed. The extension possible with such a mechanical splint tends to correct or even prevent the deformity. For the fuller realization of this point we have the plaster or other self-hardening bandage best applied from just above the ankle to well above the pelvis as a spica; many means of extension; osteoclasis; osteotomy; forcible reduction, and *brissement forcé*. If operation be necessary the last two methods are the least de-

sirable. The aim is to avoid deformity by making early diagnosis and traction from the beginning of treatment. The removal of the focus may be done by injections; arthrotomy with curetting the disease away; excision, not advisable in children because the epiphysis is almost certainly damaged; amputation when the disease is very advanced and deformity hopeless. The ordinary complications are abscess, sepsis, and sinus. The abscess should be excised when possible, otherwise widely opened, scraped and drained; if in the bone-substance, wide gouging must be done. The sepsis of joint-disease requires free opening and drainage, ofttimes amputation. Sinuses sometimes yield to drainage, asepsis and stimulation, but often require wide excision. The non-operative treatment usually requires two years in simple and three years in complicated cases.

Dr. Barton of Philadelphia began the discussion by saying that an attempt to excise a cold abscess should always be made. Dr. Dawbarn of New York pointed out that shortening is always greater after injury to the lower than to the upper end of the femur. Dr. Ochsner of Chicago regards the systemic more important than the operative treatment in the early cases. Most of his patients come from a damp, overcrowded lake-front part of Chicago, filled with tuberculosis. If he can get the family into a part of the city with dry soil, and no cellars and comparatively healthful surroundings, improvement at once begins. Dr. Sullivan of Chicago pleaded for the earliest possible diagnosis in order to avoid deformity, sepsis and amputation. Dr. Bullitt of Louisville, Ky., referred to the statistics Dr. Gibney reviewed before the International Congress in Berlin, when, under mere bandages, fair protection and good hygiene in the early days, good results were accomplished. In these later years of improved appliances still more is done.

Fractures of the Patella.—The failure of the bony union, said Dr. Barton of Philadelphia, so often resulting in non-operative treatment, leads to fracture on the opposite side, and has a medico-legal significance. Operative treatment under care has none of these objections; it has a low mortality now and has always been his choice, after waiting a few days for reaction to occur. The advantages and disadvantages of the two methods should always be explained to the patient and the responsibility of the choice left with him. No suture of the peripatellar soft tissues can be trusted. Hence, wiring the fragments with one or more pieces of silver wire is the best. The suture must not lie upon the cartilaginous surface, but simply penetrate the bone. The twisted end may be laid into a slit in the tendon. His choice as to patient is only those in good health with high resistance powers and commonly with fracture by muscular action. Prompt operation gets ahead of the organization of blood-clot and is better for the patient. If there is much damage to the soft parts small drains from the lacerated parts for a day is sufficient. Passive motion should be begun after three weeks.

Unreduced and Irreducible Dislocations.—Dr. A. D. Bevan of Chicago said that experience with old joint-injuries, with the pathological conditions found in open operations of very frequently displaced small fragments of bone intercepting the replacement of the joint has led him to try prompt invasion of the joint when all proper manipulations have failed to reduce and when the X-ray showed splintering of one or more of the bones. His data are drawn from three cases of elbow-, one of hip-, one of astragalus-dislocation, unreduced and not reducible. In pre-antiseptic days joints were left alone as a fixed rule with rare exceptions, but in these antiseptic and aseptic times old cases are infrequently opened and good results follow. In literature, however, there are few cases in which immediate exploration has been done. All his cases healed primarily, with perfect or good partial function and his conviction is that the method is surgically sound. His conclusions are: (1) Highest standard of asepsis and antisepsis; (2) free opening of the joint (of the elbow best by two lateral incisions over the condyles rather than a long posterior one with damage to the triceps tendon; of the hip best in front with separation but as little division of muscle as possible; (3) careful exploration for bone-fragments with entire removal; (4) full division of adhesions or bands, if these exist; (5) emptying the joint of clots; (6) closure without drain; (7) after-treatment in splints the same as under ordinary surgical conditions for each joint, namely, at the elbow semi-flexion and pronation; (8) responsibility of choice to be the patient's after full explanation of the dangers and possible benefits: (9) failures to reduce to be at once followed at the same sitting by excision of the joint to restore it; (10) operation when usual means have failed and before callus is cast about the offending fragments, bands and adhesions occur or clot organizes; (11) careful skiagraphic study in each case before proceeding; (12) only the old cases should be drained; (13) sterile salt solution is the only proper irrigation.

The discussion was opened by Dr. McLane of Detroit, who called attention to the entire practicability of this method on the ground of modern primary open method in all surgery, illustrated in compound fractures and tenotomy.

Dr. Blake of Chicago said that the finger must not touch any part of the joint in fractures of the patella, but instruments alone. The patella heals as do other bones; therefore, apposition by removing soft parts between the fragments and suturing the peripatellar soft parts with chromated gut and securing a fitting splint-support merely are necessary. Sterile water should be the sole irrigation. Operations should be done at once or before the clots cause adhesions. Recent clots and fresh blood can be absolutely washed from the joint. Dr. Tinker of Philadelphia said that aluminum-bronze wire is used by the Germans because it is slowly absorbed.

Dr. Ochsner of Chicago pointed out the frequency with which the patellar fragments roll outward and have clot between. The transverse incision in his hands is better by giving free access to the expansions of the quadriceps tendon which so often embraces the bone at the sides and should always be sutured. Chromated catgut is absorbed and is far preferable to wire. A rubber bandage over the thigh during the operation and until the patient is in bed prevents spasm of the muscle and damage to the sutures. Three weeks after operation he has his patients walk with aid. His operations have varied from one day to one year after the injury. The former is his choice.

Dr. Means of Columbus, Ohio, reported 9 successful cases of patellar suture. He never allows his hands to touch the tissues, and never uses wire. The incision is always adapted to the case, hence it varies. He also outlined a satisfactory early operative invasion of the shoulder for unreduced and irreducible dislocation. Dr. Barton said his fingers touch only the fracture surfaces. Sepsis in his observation always begins in the skin. An absorbable suture would probably be preferable to wire, but choice lies always in suturing the bone itself, not the tissues about it alone. The retention of the fragments free of interposed soft tissue in good contact, judicious selection of resistant, healthy cases, and rigid antisepsis are the needs.

Dr. Bevan of Chicago closed by asserting that the non-operative management is often absolutely satisfactory. In his hands a prize-fighter with each patella fractured had been cured and enabled to resume his vocation. The doctrine that all men under all circumstances should open the knee-joint is dangerous in the extreme. In skilled hands, with all possible facilities and precautions, no doubt the suture is a good procedure.

Serumtherapy in Tetanus.—Dr. J. D. Blake of Baltimore brought out the necessity of early and liberal use of the antitoxin serum in reporting five cases. The first, a carpenter, acquired the disease by a crush of the fingers, and was cured by 50 cu. c.m. The second was a lad who ran a fence sliver deeply into his thigh, and was saved by 60 cu. c.m. The next was a machinist injured by a nail and recovering after 60 cu. c.m. The fourth, a bather, forced a bit of rotten stump into his foot, part of it remaining in for a few days. He died after 40 cu. c.m. had been given, having come late under observation. A carpenter was the fifth patient, infected by nail and saved by 70 cu. c.m. The injections were subcutaneous. The organisms were identified in the blood of only two.

In the discussion Dr. Whetmore of New York City directed attention to the report in *The Annals of Surgery* of 9 cases treated at Roosevelt Hospital, all infected from toy pistols; 7 were trephined and the serum injected into the lateral ventricle, and two received subcutaneous treatment. All were "star" cases.

Frontal Sinus Tumors.—Dr. Hamilton of Columbus, Ohio, reviewed two cases of frontal sinus growth and enforced the need of early recognition and prompt operation. Commonly the neoplasms are osteomata or malignant invasions, with any possible local result, bone absorption, chronic or subacute meningitis, abscess of the brain, etc. The second case had a three-year history, no tuberculosis and no syphilis inherited or acquired, marked exophthalmos, optic neuritis, retinitis, choroiditis, amaurosis on each, especially the left, side. Upon exposure both posterior walls of the sinuses were found to be eroded; local thickening of the meninges; both orbital plates absorbed; pus in the left orbital cavity, causing the more marked signs in that eye. The finger could palpate the left petrous bone. After thorough removal most of the eye symptoms disappeared and the patient's mental and moral state cleared up wonderfully.

Dr. Dawbarn of New York stated his experience with an obscure growth in the antrum of Highmore. A tooth had been removed by a dentist for persistent pain and had a soft growth attached to its fang. No importance was attached to this. But the pain was not relieved and upon light examination a growth was appreciated. Dr. Dawbarn took a straight cambric needle in a needle holder and by forcing it through the cheek finally ascertained where the bone had been absorbed. He found the consistency here about the same as that of cartilage. The simple plan of palpating bone beneath soft parts he considers of value.

Injuries to the Head.—Dr. W. H. Earles of Milwaukee, Wis., said no accident to the head is too trivial not to need treatment, and none is too severe to be hopeless. The anatomical position of the head and the erect posture of man make the head very exposed. Simple scalp-wounds may be fatal through infection and complication. The outer and inner tables may be broken independently and often the inner with depression and meningeal or brain lesion. Frequently, there is not even a scalp-wound, yet cerebral laceration, contusion or hemorrhage may be marked. The important things to ascertain are the condition of the substance, membranes and vessels of the brain. Simple scars of lacerations may lead to chronic meningitis, headache, epilepsy, or insanity. The procedure should, therefore, be free exposure, minute investigation of bone-membranes and brain, with careful repair of damage, especially the removal of pressure by bone fragments, etc.

Laminectomy.—In spinal disease, said Dr. Samuel A. Lloyd of New York, the mechanical treatment is often too tedious, does not arrest the process and, hence, often makes operative interference necessary. In cases of tubercular spondylitis the following broad principles are applicable: Laminectomy with exposure of the disease-area should be thoroughly done (1) when the case is evidently advancing, is complicated by abscess-formation or by myelitis of any type; (2)

when the disease is posterior and paraplegia is being established. Tubercular deposits elsewhere in the body usually contraindicate operation. The cervical region is least, the dorsal and lumbar vertebra and the sacrum are next in order of advantage as fields. As a rule, the pressure will be found due to granulations, tubercular detritus, abscess, rarely to bone itself. Tumors from this point of view may be of the cord itself, its membranes or its bony canal and, hence, embrace almost any possible variety, malignant, benign or inflammatory. In general the surgeon's guides in these are the same as in fractures. Statistics give 8 per cent. deaths directly attributable to the operation. Cervical fractures have few recoveries; elsewhere the prognosis is better. If the cord is evidently crushed or cut across, as may be estimated by the sum total of the symptoms, then operation is useless, but, with the slightest outlook for benefiting the patient, it is always wise to try. Late symptoms may be due to slow inflammation, or, as in the fractures of the arches and spines, to exuberant cells. Lesions of the cord itself are necessarily complete and absolute or partial with final suspension of the function of the injured part of the cord or with renewal of the same after a variable interval. Hence, are deduced the following laws for operation: (1) If destruction is complete, no operation; (2) if partial and the patient's condition is stationary, neither improving nor retrograding, operate in the hope of some benefit; (3) if partial and rapidly extruding, operate because hemorrhage, effusion or operation may be the cause; (4) if partial, with improvement at first then stationary, operate; (5) if recovery is practically complete and late signs supervene, operate to remove the callus or other source of pressure. The damages are shock and hemorrhage. The latter is usually controlled easily. The former may be well combated in any of the modern ways and largely avoided by waiting for the signs of the original shock and concussion to pass off. In general, we should be guided not by local deformity and displacement, but by signs of cord damage inherent in sensory, motor and reflex functions. Since the true source of pressure may be extra-, or intradural fluid, rarely than bone, the contents of the canal must be exposed and inspected beyond the site of essential bone damage. Again, the membranes often require incision to evacuate foreign contents. In general, as in the cranial cavity, all sources of pressure must absolutely be removed.

Dr. Dawbarn of New York in the discussion added that he had treated one patient a year and another two hours after injury with good results. But in general immediate operation, as in skull injury, directly after the initial shock, is the best method. Dr. Hough of New Bedford, Mass., said he had cured a case presenting first paralysis of both legs, then of the right and later of the left arm. He removed the sixth and seventh cranial laminæ. The patient now has paresis of the right arm only.

Surgery in the Aged.—Dr. J. P. Tuttle of New York reviewed his experience with 163 patients aged over fifty years and 133 over sixty. The second group averaged about sixty-nine years. Two deaths had occurred from pneumonia and one from a confusion of urine specimens which led to operation on a man with advanced renal disease. The operations were many of them major, representing hemorrhoids, hernia, varicocele, resection of the intestine, fistulæ-in-ano, prolapse of the rectum, hysterectomy, etc. The anesthetic employed was ether 183 times, cocaine 30, chloroform 13. In the rest of the cases no minute of the anesthetic was made. There were no deaths from anesthesia. None of the patients was robust. None was selected for the paper. Almost all had moderate albuminuria. Fatty and epithelial casts always excluded, but only very many hyaline casts prevented operation. Celerity and rigid asepsis were always followed. Shock was often absent. Primary union was the rule. In the aged we assume either no vicious habits and good care or originally fine constitution or both. Hence, operations should be well borne.

Dr. Dawbarn of New York said first and second childhood are alike in that sepsis is extremely fatal. Constitutions made poor by alcoholism also bear infection badly.

Intestinal Sarcoma.—Quoting from statistics, Dr. C. Van Zwalenberg of Riverside, Cal., said that in 14,000 cases seen during fifteen years primary sarcoma had occurred 13 times, of the ileum 7, jejunum 3, cecum 2, ileocecal valve 1. Dr. Weir reported 2 instances in 35 resections of the intestine. His conclusions are that it occurs 1 in 1000 cases, invades the small gut usually, causes dilatation rather than stenosis, follows few of the features of carcinoma, behaves usually as a kind of infection and is difficult of early diagnosis. Wide resection of the gut and extirpation of evident secondary deposits as early as possible are the indications.

Nerve Injury.—Dr. B. B. Eads of Chicago stated the histories of several instructive cases of successful primary suture of the median and ulnar nerves. Statistically, he collected 204 cases of nerve-repair in addition to his own, distributed thus: Immediate or primary operations, 62 successes, 62 improvements, 49 failures; secondary or late operations, 61 successes, 61 improvements, 19 failures. His conclusions are that as a rule a primary suture is the better, consistent asepsis and antisepsis, no drain-tubes, no chemical antiseptics, catgut transfixion and fine silk sutures in the sheath, no tension, careful approximation, relaxation by position, removal of the restored nerve as far from the probable site of scar tissue or possible.

Retained Catheters.—In external urethrotomy, Dr. J. R. Eastman of Indianapolis, Ind., said, most surgeons retain catheter drainage from twenty-four to forty-eight hours: a few three to six days. In his own cases he had kept them *in situ* as long as twenty days in hematuria, decreasing the tension, increasing the urethral caliber

and stopping the bleeding by rest. Before the days of clean surgery, continuous drainage by the retained catheter was abandoned, because cystitis and other infections so often occurred. But since that time gradual return to it was being made. Cystitis may be caused by direct traumatic contact or by decomposition. If the instrument be inserted just the right distance and changed at intervals and irrigation of the bladder and urethra done regularly, then it can usually be prevented. Sometimes in urethrotomy the canal is too tortuous and tender to permit anything but retention. A large catheter properly managed, permits little movement within the urethra, hence, little irritation, gives little leakage, is well borne, prevents spasm, secures dilatation and usually avoids long after-treatment by keeping urine out of the perineal cut. The dilatation seems to be such that often, while a No. 26 Fr. catheter was passed, a No. 32 sound will go in easily.

Dr. Lord of Nebraska said the only contraindication is a truly septic urethra.

Dr. Guiteras of New York said that retained large catheters straighten tortuous urethras, overcome spasmodic stricture, alleviate follicular prostatitis, often aid the better healing of traumatic stricture, provide continuous drainage in fracture of the pelvis early and late when fibrous tissue may invade the perineum, soothe spasm in seminal vasculitis, introduce the patient to catheter-life very gracefully by straightening the canal, overcoming spasm and habituating the mucosa to the instrument. Cleanliness and irrigation avoid the urethritis of retention. Deposits upon the catheter should be washed off and the instrument changed. In typhoid and other severe fever to obviate frequent catheterism the retained instrument can well be used.

Dr. McLelland of Ohio rehearsed a case of prostatic spasm with retention. Suprapubic puncture with a trochar and cannula was done and a catheter passed through the cannula and left in. The drainage relieved the congestion and spasm so that large sounds could be passed. Dr. Holmes of Philadelphia mentioned a case of cystitis, sinus and vesical calculus, for which he had used a retained catheter with advantage.

Dr. Kelly of Baltimore reported a case of tubercular nephro-uretero-cystitis of the left side. The patient had suffered most from the bladder lesion. Hence, he decided to explore that first. This operation was so well borne that he determined at once to do the radical steps. Through his usual loin incision, somewhat shortened, he freed the kidney and the ureter and passed them down to the pelvic brim behind the peritoneum, through his median exploratory wound he shelled out the bladder, excised its diseased zone and after freeing the balance of the ureter removed the bladder segment, ureter and kidney together out of the median incision. The bladder was sewn up with catgut and fine silk down to the mucosa in two rows. Recovery was well under way when by accident the bladder became distended, burst and death by peritonitis resulted. The anesthetic was chloroform, but gas and ether and gas and oxygen were both being tried by him. The specimen from this case was exhibited. He also desired to say that he had never seen a case of primary vesical carcinoma. A nodule once found in the bladder proved to come from one in the uterus previously unknown which worked its way by contiguity into the viscus.

Anatomy of Hanging.—Dr. E. W. Holmes of Philadelphia said in his investigations he concluded that death is due to one or more of the following causes: Apnea, asphyxia, hyperemia or anemia of the brain, shock, cerebral concussion, neuroparalysis and, perhaps, least frequently, broken neck. It is probably painless. Electrocution appears to be fatal through universal muscular tetany—especially of the heart.

Section on Obstetrics and Diseases of Women.

Second Day—June 6th.

(Continued from page 943.)

Dr. G. C. Carpenter of Columbus, Ohio, Superintendent of the State Hospital for the Insane, read a paper on "Pelvic Disease as a Factor of Cause in Insanity of the Female, and Surgery as a Factor of Cure." He said it was early observed that pelvic disease is associated with mental changes at puberty, the menopause, and in the post-climacteric period. A close anatomic connection and intimate physiologic relationship would thus seem to be indicated. He traced the embryology of the generative and nervous systems in man and other animals, and proved that comparative embryologic development of the nervous system and generative organs show a precedence of nervous functions. The sex is not distinguishable up to the third month, while long before this time the brain, cord, and nerves have been formed and are functionating. The entire nervous system also develops from the epiblast, while the genito-urinary organs develop from the mesoblast. He showed that the older ideas as regards the cause of many forms of insanity in females are exploded in many instances. It would appear that pelvic disease is a factor in the cause of these mental changes, and that surgery is a factor in the cure of the condition. The pelvic condition should be ascertained in every case and if any disease is found an operation should be urged. This method will give to the insane woman the same advantages enjoyed by the sane.

Dr. C. H. Hughes of St. Louis, Mo., presented a paper entitled "The Interrelation of Gynecology and Neurology in Practice." He said that the advances made in bioneurologic discovery give just warrant for the statement that, with a proper understanding of this subject, there ought to be one opinion respecting the interrelation of neurology and gynecology in practice, and but one method of therapeutic procedure among both gynecologists and neurologists: that is, to treat the whole organism and every damaged part for

the best results. The omnipresence of the nervous system throughout the organism, with its afferent and efferent communications, is noted, as may be witnessed, for instance, in the interrelation of the vagus nerve and brain and the abdominal and thoracic viscera; the relation of hysteria and of a cortex lesion to its varying subcortical and peripheral abnormalities of function; the proven interrelation of pelvic and cerebral states as shown in the various phases of erotic life and evolution; and in the neurophysiologic and neuropathologic changes, both central and peripheral, of the catamenial stages and the menopause in women. Their alteration, beginning in the governing nervous system and effecting active and reactive influences revealed in a clinical symtomatology largely nervous, but also in grave pathologic changes of uterine stricture, indicate that the patient must be treated in whole, as well as in part; that there is a general as well as a special clinic on hand, a case in which the knowledge of more than one specialist is often demanded in treatment. Mere local manipulation and remedy are not all that is demanded. Woman has both a gynecic and a neurocerebral function and sphere of physiologic and pathologic influence and often deserves, when ill with local manifestation of disease, both neurologic and gynecologic treatment at the same time. The gynecologist, if he treats her all over as she deserves, should be much of a neurologist and the neurologist *vice versa*. Too many gynecologists see their patients only through a speculum and many neurologists see them only through the nervous system. Both of these classes are narrow.

Dr. A. L. Beahan of Canandaigua, N. Y., read a paper on "Tubo-ovarian Adhesions; Their Reflexes," in which he stated that there were two classes of pelvic adhesions, the massive, heavy form due to active inflammatory changes, and a milder form in which the inflammatory action is not so marked. The first form is ordinarily gonorrheal in origin. The development of these tubo-ovarian adhesions is never ushered in by severe symptoms. The first indication of the disease will be in the remote effects acting through the sympathetic nerves on distant organs. In these women a careful examination under an anesthetic is indicated, and if pelvic trouble be found a radical operation should be performed. Continued trouble here will ultimately disturb the nervous system and hysterical symptoms will sooner or later appear. The differential diagnosis of this border-line disease is paralleled by insanity caused by structural changes in the appendages. The former consigns the patient to chronic invalidism, misnamed neurasthenia or hysteria; the latter excludes her from society or even ostracizes her from home.

Dr. Edwin Ricketts of Cincinnati, Ohio, read a paper entitled "Gall-Stones and Diseases of the Gall-Bladder and Nervous Symptoms Resulting Therefrom." He said the peculiar nervous symptoms, at times indescribable, accompany the presence of gall-stones. These stones are usually found in the excretory apparatus of the liver, the bile-ducts, liver-cells, adventitious cysts, or in the intestinal tract. The contents of the gall-bladder, with or without gall-stones, may become infected by the bacterium coli communis or by a pyogenic streptococcus which gains entrance from the duodenum or through the blood of the portal vein. The prevalence of gall-stones in insane subjects is a recognized fact. Gall-stones should be removed as soon as diagnosed. Distended gall-bladders that fail to be emptied as the result of internal medication alone, as by the use of calomel, or in combination with massage through the abdominal walls, should be drained by means of a cholecystotomy.

In the discussion Dr. Porter of Indianapolis said that in this class of nervous patients the gynecologist should call in the neurologist and the two work together. He called attention to the nervous symptoms induced by the menopause artificially produced, which at times even amount to a true hystero-epilepsy. Before proceeding to operation in nervous cases a consultant on nervous affections should be called in, and every insane hospital should have a visiting gynecologist.

Dr. Shoemaker of Philadelphia remarked that pelvic disease, or pus-tubes, fibroids, and the like, induce anemia and deterioration of blood, and for this reason if for no other operation would be indicated to relieve the local and general condition, if not the nervous symptoms.

Dr. Eastman regards insanity and cancer as the two most important questions of the day in gynecology.

Dr. Benjamin of New Jersey stated that many ovaries are being removed for the relief of pain. He does not believe in the removal of organs in order to cure pain. Operations are not done for neuralgia over the eyes or in the chest. In these pelvic cases he gives the remedies used for neuralgia elsewhere and has excellent results.

Dr. Zincke of Cincinnati would remove all disease before the patient is admitted to the asylum. He would not operate on every case of gall-stones that was diagnosed.

Dr. Carstens of Detroit said that if the case was diagnosed early and the cause removed early, the symptoms would not develop. It is not the gynecologist, but the general surgeon who removes the ovaries to cure insanity. The gynecologist has learned his lesson too well to do this.

Dr. Baldy of Philadelphia said the whole matter could be included in two questions: Do gynecologic troubles cause insanity? If so, will operation cure it? He is convinced that gynecologic troubles do not cause insanity. He thinks it is unnecessary to examine every patient who enters an insane hospital. There is probably a greater proportion of women in health with pelvic lesions than in the insane asylums. The only justification for operation is when the lesion is giving symptoms. Insane cases following parturient and puerperal lesions will recover. This is not true of cases of other origin and I desire to protest against the effect of operative procedure.

THIRD DAY—JUNE 7TH.

Dr. A. H. Goelet of New York read a paper on "Aseptic Minor Gynecology with Demonstrations." He stated that it is easy enough to be clean in gynecologic work. Patients are easily infected by carelessness in this respect. Cleanliness in every-day gynecology is absolutely essential in office-work and in every gynecologic examination, not only for the protection of the patient, but for the physician also. Cleanliness in every detail always reverts to the benefit of the physician, because it is pleasing to the patient and inspires confidence. The examining-chair or operating-table should be arranged and kept ready for use. The instruments are to be selected for use and placed in a shallow dish half-filled with an antiseptic solution. All articles likely to be needed for the examination, such as sterilized cotton swabs for sponging, gauze prepared for tampons, prepared cotton-wool tampons with strings attached, should always be placed conveniently before beginning the examination. Such remedies as may be needed for application are to be in readiness. A reservoir containing an irrigating solution must be filled and placed in position so as to be convenient. He has devised a special form of air-cushion for operative and office-work. This is to be covered with a clean cloth for each patient, and obviates wetting the patient's clothing. The hands must be thoroughly clean in order to avert danger, the staphylococcus is always present and often the streptococcus. Ordinary soap and washing will not cleanse the hands. The author employs a liquid soap with the brush. For douching he uses an ordinary percolator with a rubber tube attached. The character and significance of every leucorrheal discharge should be investigated and understood and an antiseptic irrigation of the vulva and vagina should precede every digital examination. Asepsis in the examination at the patient's house is just as important as at the office, and for this purpose he has devised a special aseptic case.

The Nominating Committee reported the following names: For chairman of the Section, Dr. H. B. Newman of Chicago; for Secretary, Dr. C. S. Bonnifield of Cincinnati.

"The Symposium on Cancer of the Female Generative Organs" was opened by a paper read by Dr. L. S. McMurtry of Louisville, Ky., entitled "The Prophylaxis and Diagnosis of Cancer of the Uterus." He stated that there are two varieties of cancer of the uterus pathologically, namely, epithelioma and carcinoma. The epithelioma shows squamous cells and infiltrates the deeper tissues; the carcinoma involves the structure of the uterus and invades the glandular substance. Erosions of old cervical lacerations are often the starting-point of carcinoma. The disease begins near the external orifice and infiltrates the tissues. The surface is at first smooth or nodular. Ulceration usually occurs early in the course of the disease. The cauliflower growth bleeds freely and advances rapidly. The process of invasion is usually by continuity of tissue. Adenocarcinoma of the uterine body is localized in the early stage in the mucous membrane. Later the uterus increases in size, the entire cavity is filled, and the muscularis is invaded. The diagnosis must be made from the subjective symptoms, examination by touch and sight, and the microscope. In the initial stage of uterine cancer there are no symptoms. As the disease advances the three classical symptoms, hemorrhage, discharge and pain appear. The hemorrhage is a result of ulceration and is usually the first symptom to appear. Slight at first, it is later profuse and alarming. The discharge is at first thin and watery; later it is turbid, bloody, and fetid. Pain is by no means constant and may be absent altogether if the disease is limited to the cervix. Pronounced pain, as a rule occurs in the advanced stages of the disease. Irritable bladder, cystitis, and alternating diarrhea and constipation are late symptoms of the disease. The cancerous cachexia is now present. In the early stage of the disease the diagnosis is difficult at times. The senses of touch and sight must be employed. Cancer is preeminently a disease of the child-bearing woman. Microscopic examination is invaluable and must be employed in every obscure case. The cervix is the usual site of invasion. Primary cancer of the corpus uteri is comparatively rare. Bacteriologic examination has added but little to our knowledge of this disease. Recurrence is apt to follow late operation. The patients often come too late for success. As a prophylactic measure, ulcerations, erosions, and lacerations of the cervix should all be repaired and the parts kept perfectly clean.

Dr. R. B. Hall of Cincinnati, Ohio, read a paper on "The Technic of Vaginal Extirpation for Cancer of the Uterus." He urged the necessity of careful preparation of the patient to be subjected to vaginal hysterectomy. The function of the kidneys should be carefully noted and the patient should be kept under care for a few days before operation. The extreme lithotomy position should be used, and the anesthetic should be chloroform unless the drug is contraindicated. If the case is one far advanced, with great sloughing, or one of epithelioma with a large mass of cancerous tissue, the operation may be done in two stages. The perineum is retracted by a short, broad speculum, and the vagina thoroughly scrubbed and carefully sterilized. A short curette cuts away the soft tissue and the thermocautery is applied. Ten days later the final operation may be performed, and the superficial tissue will be found comparatively healthy. Thorough curetting and the subsequent cauterization adds materially to the safety of the patient. The cervix is fixed with a strong volsellum, and the mucous membrane divided around the cervix one-half inch or more from the diseased tissue. The mucous membrane is then dissected back and the bladder freed. The wound is widely separated by the fingers introduced and separated; this displaces the ureters outward. A gauze pad is then

passed into the cavity and rests upon the uterus. The posterior vault is opened and gauze introduced behind the uterus. The first ligature of heavy silk twist is introduced by means of the Cleveland ligature carrier. If the disease is more marked on one side than on the other, the healthy side is first tied. A good button of tissue is left and one end of the ligature is cut short. This can be repeated on the other side alternately until, finally, a ligature passes over the top of the broad ligament. It is important not to include too much tissue in any one bite. The tubes and ovaries should always be removed. The operation is almost a bloodless one. An ounce or two of blood is all that is lost. The gauze prevents prolapse of the omentum and intestine. The bunch of ligatures is then tied together and the peritoneum closed above the ligatures by a suture running to the middle line and drawn taut. A corresponding suture on the other side completes the closure. The dressing of gauze which is now introduced is not removed until the fourth day. It is then not replaced, but a douche is given every three or four hours after micturition. He does not believe in the necessity of always catheterizing the ureters.

Dr. J. B. Deaver of Philadelphia read a paper on "Combined Abdominal *versus* Vaginal Hysterectomy for Carcinoma." He stated that the choice of route must be decided in every case. The glands should be extirpated as well as the diseased tissue, hence the abdominal route is to be preferred. The vaginal method will answer in some cases. The incision must be a long one and the field freely exposed. Abdominal hysterectomy offers the following advantages: It affords the only opportunity for removal of the pelvic glands. The author here gave a brief review of the anatomy of those glands. There are two chains of lymphatics to be considered, an upper and a lower one. It also affords a better area for complete extirpation of the carcinomatous tissue. There is lessened danger of injury to the ureters. Catheterization of the ureters is unnecessary and therefore an uncertain and frequently impossible step in the operation is avoided; further, the danger of kidney infection is avoided. There is lessened danger of hemorrhage on account of a better command of the field of operation. Consecutive hemorrhage is less liable to occur. The danger of infecting the peritoneum is lessened. The author has serious doubts as to the possibility of sterilizing any vagina. Most cases of abdominal hysterectomy need no drainage, but, if this be required, it is always best to make it suprapubic. In total extirpation the peritoneum can best be closed from above. There is no danger of prolapsing bowel. Vaginal hysterectomy is only applicable (1) in early carcinoma confined to the cervical or uterine canal; (2) when the uterus is small and easily movable. It is contraindicated when the cervical or uterine canal is affected and there is disease of the uterine appendages, as adhesions, pyosalpinx, ovarian cyst, or fibroid tumor.

Dr. W. H. Humiston of Cleveland, Ohio, read a paper entitled "Cancer of the Uterus." He urged the great importance of the general practitioner recognizing early malignant disease of the uterus. Immediate and complete operation should be insisted upon. Adenocarcinoma is the only form that involves the body of the uterus and it is the most common cause of metastasis. The epitheliomatous variety is comparatively slow to give rise to metastasis, and offers the best chances against recurrence after operation. If the operator waits for the classical two symptoms it will be too late to cure the patient. Adenocarcinoma of the cervix is the form of cancer most to be dreaded. There are three modes of recurrence: (1) By metastasis; (2) by incomplete removal of the infected areas; (3) by infection or direct implantation of malignant cells in previously healthy tissue at the time of operation. The practical import of this paper can be summarized thus: The importance of early differentiation of maligant growths of the cervix. Careful consideration of the importance of the lymphatic vessels and glands in their capacity as drains of different portions of the uterus. There are two distinct groups of lymphatics to be looked for. When the disease has passed beyond either group all chance of complete recovery is gone. Abdominal section with complete removal of the special groups of lymphatics alone offers a chance of recovery.

Dr. W. R. Pryor of New York spoke on "The Treatment of Cancer of the Uterus." He stated that in America cancer destroys 30,000 women annually. He believes the disease is due to a parasite, although this is not proved. Vaginal hysterectomy is firmly established in the opinion of surgeons, and yet it gives a mortality of 10 per cent. in the hands of the best operators, and recurrence is frequent. Hence, this operation cannot be endorsed. Amputation of the cervix also gives unfavorable results, although better than vaginal hysterectomy. It must also be prohibited. The operation is performed mainly to prevent recurrence and not so much for the disease itself. If the diagnosis is plain the case is a late case; if the diagnosis is obscure the case is an early one. Only in an early case is vaginal hysterectomy serviceable and even here its utility is doubtful. Byrne's method of electrocautery is valuable in certain cases. Other methods of treatment are to be condemned. Vaginal hysterectomy for carcinoma of the fundus gives a considerable degree of immunity. The vaginal operation, to be successful, must remove the uterus, appendages, glands, and upper third of the vagina.

Dr. Boldt of New York, in the discussion, said that cancer of the supravaginal cervix is the most difficult form to recognize and usually advances further before being recognized. The technic of vaginal hysterectomy as given by Hall is most beautiful, but the question arises, How many patients so operated upon remain free from recurrence two years afterward? A strong, short-jawed clamp will allow more tissue to be removed than will the ligature.

Dr. Baldy of Philadelphia said that there is nothing so irrational as vaginal hysterectomy however done. In arriving at conclusions it is not right to select cases, but to consider all cases of a class together. Cervical cancer and fundal cancer are two distinct classes. All cases of cervical cancer, in his experience, die sooner or later, either primarily or by recurrence. Fundal cases, with the exception of those who die under the operation, are cured. It is not fair to consider these two groups of patients together.

Dr. Carstens of Detroit believes that men who employ the abdominal method will have just as much recurrence as those who do the vaginal operation, and yet he does not like the latter operation. He has just as good results from curetting and cauterizing as from the major operation. In every case the prognosis must be made just as bad as possible.

Dr. Joseph Price of Philadelphia said that malignancy is never cured. On the Continent the diagnosis of cancer of the cervix is often made in simple erosion of the cervix. Hysterectomy is then performed, and these cases recover permanently. The free use of the curette and cautery gives as good results as any other treatment. In extirpation recurrences are common, but the deaths are easier.

Dr. Byrne of Brooklyn denied the legitimacy of hysterectomy for cancer of the cervix in any case. According to records it is not justifiable treatment. Excision of the diseased part by the heated knife is what he advocates. Deep cauterization and charring of the parts that are left will permit the patient to live many years. Some of his patients are living to-day, fifteen or twenty years after their operation.

Dr. H. A. Kelly of Baltimore read a paper on "Resection of the Ureter," in which he dwelt on the importance of the ureter as an emunctory and the danger of injury to it in abdominal operations. It may be cut on the surface of a fibroid uterus or be ligated far out with the ovarian vessels or torn in cancerous tissue. After an injury of a ureter it is first necessary to note if it be a dead ureter, that is, if there be no escape of fluid from it. Pass the hand into the abdomen and ascertain if the patient has a normal kidney on that side. If this be sclerotic or functionless, do not do a delicate operation. Uretero-ureterostomy is done when both ends of the cut ureter are accessible and the ureter has not been resected. Ureterocystostomy is done when the ureter is partially destroyed or one end is not accessible. Recently the author hos contsructed ureteral guides to enable one to suture the ends of the cut ureter accurately together, and, secondly, to bring a ureter of smaller caliber to fit a dilated ureter below. The instrument is introduced into the upper end of the ureter through an opening in the ureteral wall (ureterotomy) and stitches are passed through the edges of the divided ureter and the two brought together. He would never drain the abdomen after doing a ureterotomy. These instruments can be used very successfully in the performance of ureterocystostomy, being introduced through the bladder and the ureter pressed forward upon it, the end then being withdrawn into the bladder.

Dr. Dunning of Indianapolis reported a case of injury of the ureter in which he introduced a uterine sound through the bladder into the ureter and drew the latter down into the bladder. In another instance of ureteral injury he was compelled to extirpate the kidney.

Dr. Boyée of Washington stated that a number of operations of this kind had been done for other conditions than operative accident, as after childbirth or to correct abnormal openings in the ureter. Thus far there have been about 80 ureterocystostomies done. The best method in ureteral injury is to suture ureter to ureter; the next best consists in suturing ureter to the bladder. The great danger of the operation is too great tension of the ureter. It is also important to make the anastomosis into the bladder as oblique as possible.

The Symposium on "Inflammatory Diseases of the Female Genitalia" was opened by a paper by Dr. L. H. Dunning of Indianapolis, Ind., entitled "Acute Senile Endometritis." He remarked that the disease as described by Skene is essentially a chronic one, and does not include the cases described in this paper. There is an absence of hemorrhage in Skene's class of cases. The pathologic findings of the cases of the author show they are acute in nature and that they correspond to the cases described by Mundé. The author reports two cases showing a clinical history similar to cancer. In one case there was a cystic degeneration of the ovary and in the other a diseased tube and ovary with mild pelvic inflammation were present. The disease spreads by infiltration from contiguity. The characteristic pathologic features are thickened endometrium, increased vascularity, small round-celled infiltration, diminished glandular tissue, and degeneration of the coats of the vessels of the muscularis. There is not any increase of connective tissue or hyperplasia.

Dr. J. R. Guthrie of Dubuque, Iowa, read a paper on "Inflammation of the Fallopian Tube, with Special Reference to Specific Origin." He stated that the Fallopian tube has been long and persistently neglected. He then gave a brief history of the disease as culled from literature. Among the existing causes are direct injury, sudden checking of the menstrual flow, infection by the gonococcus, streptococcus, and staphylococcus. Latent gleet in the male may cause an acute infection in the female. The development of the disease is of almost incredible rapidity. Noggerath's dictum that "once infected, always infected" is a safe rule to follow. Tubal disease is largely of gonorrheal origin. The disease may be a simple salpingitis or a parasalpingitis may result. The author suggests that a committee be appointed to investigate the ravages of gonorrhea in the female. Syphilis may kill its thousands, but gonorrhea its tens of thousands. The

importance of gonorrhea in the production of tubal disease has not been appreciated.

Dr. A. H. Cordier of Kansas City, Mo., presented a paper on "Tubercular Peritonitis," in which he remarked that primary tubercular peritonitis may be produced by the presence of the tubercle bacilli in the blood. The cheesy masses may or may not contain living bacilli, but most of them at an early date contain spores which may produce trouble. In the early stage of the disease the ascitic fluid is bloody, showing a certain amount of acute inflammatory action. The quantity of fluid varies from a few ounces to several gallons. The pleura is more frequently involved than any other tissue by the tuberculous process. In tubercular peritonitis ascites is not as great as in cancer, nor is it as prone to become bloody. Pain is absent in many cases and may simulate gastro-intestinal colic. In some cases it is acute, with exacerbations simulating an acute septic type of peritonitis. In some cases the patients do not lose weight but may even gain in weight. Negroes are especially prone to this disease. Typhoid fever is the one disease most liable to be mistaken for this condition. In chronic cases diarrhea is apt to ensue. Constipation is noted in other cases. Sluggishness in circulation is noted locally and marked diapedesis is present. All fluid should be sponged out at the time of operation. Pockets must be opened, pus drained, and the abdominal cavity flushed out. Constitutional remedies should be used in all cases.

Dr. Philander A. Harris of Paterson, N. J., presented a paper entitled "A Plea for More Frequent Avoidance of Exsection of the Ovaries in Connection with Resection of Diseased Tubes." He stated that many gynecologists who began by removing the ovaries with the tubes are continuing to do so as a routine practice. Only a small proportion are now removing the tubes and leaving the ovaries. He claims that the good results which have followed removal of both tubes and ovaries for disease which was forming in the tubes can in most cases be secured without sacrificing the ovaries, thus preserving for such patients as much ovarian tissue, menstruation, and consequent ovarian influence, as possible, and not entirely, and so often unnecessarily, depriving them of the possibility of conception. He divides all conservative cases into two classes: (1) Any operation in which a portion of the tube is removed between the fimbria and the uterus, which he terms *amputation of the tube;* (2) cases in which an incision is made into the uterine wall and the tube removed, the uterine incision then being closed, which he terms *excision of the tube.* Excision neither arrests ovulation nor menstruation, but prevents fecundation. Pregnancy is possible if the stump remains patent. Complete removal of the tubes and ovaries results in arrest of menstruation and ovulation and thereby induces a series of phenomena indicative of the change of life. The patency of the tube has been noted in many cases after operation. Septic troubles may result from this condition and the symptoms of the disease persist after the operation. He believes many such stumps either have or subsequently acquire an ostrum abdominale. Removal of the disease from the Fallopian tubes and uterine sinuses will cure the disease in many cases without removal of the ovaries.

Dr. Joseph Price of Philadelphia presented a paper on "Appendicitis Operations in Young Women and Girls." He stated that his paper was a short one offered to invite discussion. It was formerly thought that appendicitis was more common in males than in females. He now believes that the proportion is about equal. Young students seem very prone to the disease. At times it occurs in several members of one family. Some cases in women are postpuerperal in origin. In about 9 per cent. of pelvic disease the appendix is involved and requires removal with the uterine appendages. It is unsafe to wait for subsidence. In such cases sloughing and abscesses will result. It is difficult to urge the profession to prompt interference. Certain localities seem to predispose to the disease. Thus, it is common in Morristown and West Chester and in a broad district of Philadelphia. Early interference always results favorably.

Dr. Dudley of New York stated that he is working in conservative ovarian surgery and has had 145 consecutive operations without a death, and 25 pregnancies have followed. In five cases he has removed the appendages, sewed over the stumps, implanted a section of an ovary in the fundus uteri, leaving one-half of the ovary dependant in the uterine cavity. Four of these women have continued to menstruate. In none of the five has the ovary been thrown off from the uterus, and in none have the symptoms of the menopause followed.

Fourth Day—June 8th.

Dr. B. B. Massey of Philadelphia read a paper on "The Treatment of Menorrhagia (Dysmenorrhea) of Pelvic Origin by Electricity." He strongly protested against the teaching of the text-books and journal articles which represent that dilatation of the cervix uteri is the preferable treatment of organic types of dysmenorrhea. He quoted instances in which this method of treatment was not only unnecessary and ineffectual, but actually harmful. He claims that electricity yields the best results in this condition and described in full the method of its application.

The Dosage of Orphol.—In all the instances in which the fecal discharges are unduly offensive orphol is exhibited, but usually in quantities too small to produce the best results. Bearing in mind the innocuous nature of the drug, the rapidity of peristalsis in most cases in which it is indicated, and the amount of material to be disinfected, the remedy should be given in relatively large doses (10 to 15 grains for adults) and frequently repeated.

THE PREVENTION OF DYSTOCIA DUE TO FETAL AND PELVIC DISPROPORTION.[1]

BY EDWARD A. AYERS, M.D.,
OF NEW YORK.

LOOKING at the practice of obstetrics from a broad point of view, for the purpose of strengthening and improving its weaker parts, one cannot but be profoundly impressed with the importance of the subject of dystocia due to fetal and pelvic disproportion; painfully impressed with the careless inattention generally given it, and enthusiastically impressed with the possibilities of improvement in the management that will reward conscientious effort at prophylaxis. To such dystocia must be attributed a large proportion of obstetrical diseases and deaths. Exhaustive labors, consequent hemorrhages, sepsis, forceps, version, major operations, ruptures, lacerations, gynecological sequelæ, and all the possible injuries to the fetus, from cephalhematoma to death, make up a list that is almost the catalogue of obstetrical evils.

I wish to consider briefly the subject in two divisions. First, to what extent can we foresee the outcome of fetal passage through the maternal pelvis? Second, to what extent can we, by means of such foresight, prevent the evils that threaten?

In multiparæ, who should be considered apart from primiparæ, we have as aids to prognosis the previous history of labors, and in both classes parental characteristics, pelvimetry, fetal palpation, cephalometry and tentative engagement of the fetal head—Müller's test.

If a pregnant woman has had one or more children we should seek to learn what was the presentation, the length of time of the first stage of labor, when the amnion ruptured and why, how long a time it was from the beginning of regular and strong pains before delivery, what was the shape of the child's head when born, how much of a caput was formed, if forceps were used, and the weight of the child. It will be seen that the main purpose in these inquiries is to learn how near to obstruction the fetalo-pelvic proportions were. If the child weighed, for example, seven pounds and there was no head-molding, nor special effort in delivery, it would be very unlikely that there would be any obstructive difficulty in the coming labor, even although the child might prove larger by one pound. But, if marked molding and use of the forceps entered into the history, the coming labor would be classed as uncertain, for a larger child might not even engage at the brim.

There are, in some families, variations in the weights of successive children at birth of from one to three pounds, excluding immaturity of some of the children. But such extreme differences are very rare, and we can rely upon the rule of slight, but progressive increase of weight from youthful parentage up to thirty-five years and decrease thereafter. The problem of forecast in primiparæ is much more difficult, there being no labor-histories by which to gauge proportions.

Parental Characteristics.—It is quite as profound a statement that, as "a tree is known by its fruits," so is the fruit to be foreknown by the tree. General characteristics of parents is a very interesting study bearing on the size of offspring. In the lower animals, where definite strains are sharply defined it is a certainty what the physical characters will be in the young.

In man the tangled skein of cross-breeding greatly confuses the problem of offspring type. Regarding the physical characteristics of the parents I consider the bones as most helpful in forming a prognosis of fetal size at birth. The heaviest children are generally born of parents with large bones. The parents' features are massive, their wrists and ankles are large, and their weight is decided and is largely due to the bones. If with such parental structures there is a mutual family history of high intellectual development, we may expect large head diameters in the children at birth. The reverse of light frameworks holds good for smaller and more easily molded fetal heads. I shall refer again to this matter of the bones under pelvimetry. Where the parents are of opposite types, I believe the mother's characteristics will preponderate. The larger the number of members of a family who can be considered on both sides, the surer becomes the basis of estimate of what the fetus will be at birth. I believe that the father is not given due consideration as a rule. Perhaps, in hospital work, because he is an unknown quantity. Engelmann has stated that dystocia was greatly increased in the case of Umqua Indian women impregnated by white men.

Parental nutrition, more particularly that of the mother during pregnancy, has much to do with fetal size at birth. Prochownick's theory regarding diet, that the use of nitrogenous food from the beginning of the seventh month would so retard osseous growth as to avoid dystocia, no doubt has considerable truth in it, although we must feel that the fetus will generally act as a true parasite and get what it wants if there is any of it to the sacrifice of the mother's

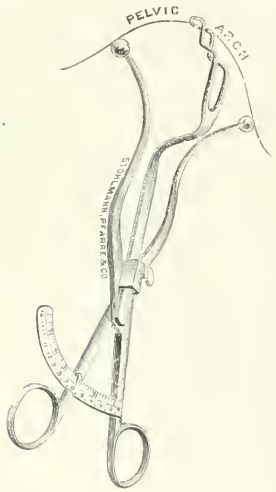
[1] Read before the Section on Obstetrics and Gynecology of the New York Academy of Medicine, April 26, 1900.

needs. Hard work and starvation are more apt to induce premature labors than smaller children at full term. Excess of fat in the mother increases the amount of soft tissue in the pelvic canal, but more materially causes dystocia in that the dynamic force in expulsion is weak. So, likewise will anemia, chlorosis, or other weakening conditions affect expulsion. Some women get muscularly weak, "soft," through the lack of exercise in the heavy months of pregnancy. The loss of *vis a tergo* is the equivalent of a large head.

Pelvimetry.—Pelvimetry partakes of both science and art, and is the basis of calculation of pelvic caliber; but it always includes the algebraic *x* in the equation. The external measurements are but an argument of probability.

It may be stated, as a rule, that we are more liable to error in estimate of the inlet diameters when the external measurements are large than

Fig. 1.



Pelvimeter.

when they are small. This for these reasons: (1) When the external measurements are under the average, or even what we consider proper proportion in a given case, our suspicion of coming trouble is aroused, and we make a very careful study of the case. When the measurements are large we are lulled into superficiality in internal examinations. (2) Large external measurements accompany heavy bony framework, and large, thick bones encroach further upon the pelvic caliber than light bones of the same outside dimensions. I have seen this markedly exemplified in some of my extreme cases of dystocia, and have been led thereby to give greater weight to what is stated here regarding the consideration of the skeleton in general.

To what extent should the external measurements determine the amount of care exercised in securing internal measurements? I can find but one answer—to no extent, so far as lessening the latter, but, in certain cases of asymmetry, they should extend the examination. But perhaps more will be accomplished generally if we do not make the standard too arbitrary. When a mother has had a satisfactory delivery-history we need not make thorough internal measurements. And, further, where we find the promontory beyond the reach of the second finger, and the tentative engagement of the fetal head satisfactory, it is not necessary to take all the internal measurements. When the plane of the symphysis lies out at the upper border, or in at the lower, as one pleases to express it, if this is not noted, we might conclude from the diameter of the diagonal conjugate that the vera is shortened, whereas just the reverse would be true. And conversely as regards the plane of the symphysis, the vera would be short just when the diagonal is long.

Measurements of the pelvic outlet, I believe, are not generally taken. Inattention to this will, although rarely, lead to unexpected trouble. The pelvis may be funnel-shaped, wide at the inlet and narrow at the outlet. I recall two cases, in one of which the child was delivered by Cæsarean section and in the other by symphysiotomy. In both the fetal head passed the brim without special difficulty. I know of no dyscrasia that should suggest this form of pelvic deformity. Clinically, we must always give attention to the width of the pubic arch, the interischial and coccygopubic diameters when examining for the diagonal conjugate.

Practice will generally enable one to suspect outlet-contraction at this time, and actual measurements may be taken. I take the liberty of exhibiting a pelvimeter which I had constructed for taking these measurements. With the upper bar in place the instrument measures the width of the pubic arch at a given level below the supremity of the arch, giving a purely arbitrary, but fixed plane of measurement. By removing the upper bar the internal diameters of the middle plane of the true pelvic basin—of the ischiæ and of the coccygopubic—can be taken with accuracy.

Abdominal Palpation.—This will enable us to only approximate the true dimensions of the fetus and particularly its head. This approximation will advance *pari passu* with practice. In cases of large pelvic space the fetus generally lies low in the inlet after the thirty-second week, but not always. In cases of contraction of the conjugata vera the head always lies high, is freely movable, even has a tendency to lie a little to the right or left of the center, and, because it lies high, is apt to increase the degree of anteversion of the uterus as a whole.

Cephalometry.—When all knowledge of pelvic dimension that our skill can obtain has been se-

cured, we have but one-half of the equation solved. The volume and diameters of the fetal head compose the other half. The variations in head diameter in different cases are not as great as those of the pelvis, but they are sufficient to require as approximate a measurement as we endeavor to obtain of the pelvis. The efforts of Ahlfeld to estimate head dimensions by measurement of the distance from coccyx to vertex, of Dubois by the length of pregnancy, and of Gönner and Bruyère by measurements of the fetal feet, have all proved useless. Perret claims that the biparietal diameter is 25 mm. less, in the average, than the occipitofrontal diameter, and that he can, with his cephalometer, secure the latter diameter with satisfactory accuracy. He palpates the head at the inlet in the ordinary manner and applies the tips of the instrument to what he decides to be the occipitofrontal diameter, notes the distance, and then pinches up the skin of the abdomen and subtracts its thickness, as determined by actual measurement, from the given diameter. He then subtracts 25 mm. from this, which gives the biparietal diameter. All of this assumes that the head lies in a normal balance between chin and occiput extension and that the occipitofrontal diameter can be palpated from above the pubes. As a rule this would be a fair assumption.

In certain patients, such as have thin abdominal walls and flaccid uteri, this measurement of the occipitofrontal diameter can be taken with accuracy. In those with tense uteri, which are distended by amniotic fluid, and thick, or tense abdominal walls, the degree of accuracy would be much less. Again, the variation in some cases between the occipitofrontal and biparietal ratio would be more or less than 25 mm.

Perret reports from the published cases of himself, Dubresay, Constans, Denys and Weill, the results in 186 examinations. In 36 of these the biparietal diameter, as estimated, was correct. In 140 the error was not greater than 5 mm. In 10 the discrepancy was over 5 mm. He suggests an *argumentum ad hominem* in stating that of these 10 cases 8 were in the list published by Denys, which might be taken to mean that the results depend upon individual skill. One case gave an error of 7 mm. due to the unfavorable condition of the patient. Taken at their face value, these results are remarkable and call for active and careful verification. In 94.6 per cent. the error was not over 5 mm.—a little less than one-fourth of an inch. Combining such head measurements with the accurate measurement of the conjugata vera that can be obtained with Hirst's pelvimeter should result in a long stride toward scientific accuracy in ascertaining pelvic and head diameters and proportions.

Müller's Test.—There are two methods of directly testing, during pregnancy, the question of engagement and passage of the head during labor. One, by placing the fingers of both hands above the pubes and pressing the head into the inlet, the other by holding the fingers of one hand against the head in the vagina, with the uterine wall between fingers and head, while the other hand presses the head down from above the pubes. In markedly contracted pelves the head stops absolutely when it comes against the brim. In the spacious pelvis the head is stopped gradually. There is, of course, every grade between these extremes of tentative engagement. The chief difficulty for the examiner is in estimating the effect of the soft parts in resisting in-pressure of the head. Here is where the results will largely depend upon the amount of practice one has had, and I believe that all experienced obstetricians will agree with me in the statement that very accurate opinions can be formed, not only as to absolute obstruction in extreme cases, but as to whether much, or little molding, will be required, if one has practised long and faithfully.

Lastly, it may be stated, that, where the lowest part of the presenting head reaches a plane on a level with the subpubic arch and parallel to the plane of the inlet, it may be expected to engage in labor.

Speaking from the standpoint of the specialist, of the obstetrician who has worked long and carefully to attain the utmost skill in diagnosis, is it not time for us to readjust our attitude toward this question of head and pelvis dystocia? Instead of being guided by the question of duration of pregnancy, a question that is so hard to solve with accuracy, should it not be our aim to place chief reliance, and much greater than heretofore, upon the physical examination? Estimation of the duration of pregnancy by calculation from the last menstruation, quickening, nausea and abdominal distention has always been exceedingly unsatisfactory, and can never possibly become accurate, owing to the variations in growth for a given period of gestation. We must learn to rely upon actual measurements and tentative engagement of the fetal head to determine, not the period of pregnancy, but the question of dystocia. Incidentally this would enable us to learn also of conditions that are the equivalent of longer time, such as hydrocephalus.

Any practical results from the above carefully-applied efforts to make early diagnoses of dystocia must obtain in either *the restriction of fetal growth, the induction of labor, or preparedness for obstruction in labor.*

The Restriction of Fetal Growth: Diet.—If, by means of diet, we can restrict the growth of the fetal body and retard ossification of the cranial bones during the last six weeks of gestation, and, at the same time, enable the child to escape the dangers of prematurity, that is, control the production of a small but mature child, we will secure the very best method obstetrics can devise for avoiding the dystocia due to fetal head and maternal pelvic disproportion.

Rowbotham seems to have been the first to have experimented in diet for the prevention of dystocia, publishing successful reports in 1841. He restricted the diet largely to vegetable acids

with the intention of preventing the formation of earthy salts. In 1889 Prochownick published a paper, "An Attempt to Replace Artificial Premature Delivery," in which a diet was advocated that proscribed entirely water, soups, potatoes, cereals, sugar and beer. It permitted for breakfast a small cup of coffee and about six drams of zwieback. For lunch any meat, eggs and fish, some green vegetable and fat, some salad and cheese. For the evening meal one and one-half ounces of bread and butter, as wanted, were added. Fluid was limited to 12 to 15 ounces of red or Moselle wine a day. He began this diet in his first case seven weeks before labor, which occurred at term. Four previous labors had resulted in failure, two from perforation and version, and two from induced labor. This labor resulted well, the child weighing 5 pounds, and "acting like a mature child." Horn[1] has since reported a series of 47 cases of treatment of dystocia by Prochownick's diet, 13 of which were by Prochownick, in which all the mothers and children lived. In one of Prochownick's cases the diet failed to cause restriction of growth. These results are very encouraging. I have not yet tested the method in my own practice, but hope to do so ere long. We are all familiar with the effect of hard work and scanty supply of food upon the period of pregnancy and the growth and vitality of the child. This combination must not be confounded with Prochownick's system of feeding, which, he claims, is not a starvation diet at all, although possibly some of our well-cared-for patients might think this a distinction without a difference. I know of no case in which the diet has caused labor to occur ahead of time.

The Induction of Labor.—By the induction of labor we have the one other, and certain, preventive of dystocia, the chief, and almost only objection to its employment, being the risk of fetal death from immaturity. It is unquestionably a fact, however much we may stand theoretically opposed, that induced labor takes precedence over all other measures in threatened dystocia in obstetric practice amongst the well-to-do. There is no denying, too, that this represents a distinct element of sacrifice of the child's interests as compared with major operations at term. Obstetricians likewise show a similar preference, usually in proportion to their inexperience with the two major operations. But if, considering the question raised in this paper, we extend the field of induction of labor to include the minor grades of contraction, those belonging to forceps delivery, then this distinction between the major operations and induced labor grows less, inasmuch as the degree of prematurity of the child at birth is slight.

The problem to be answered is: Does a child born two to four weeks before term have a better or poorer prognosis than born at term after hard labor and delivery by forceps or version? There is not time to enter into detailed argument in answer. It would always depend upon the conditions in each case, the element of greatest variability being the physician in the case. An important feature of the question is that in cases at term which lie between possible forceps-delivery or symphysiotomy or celiohysterotomy, many would be deliverable by forceps-traction if the advantage of head molding could be secured. But the head just misses engagement, so that all the benefit of reduction in diameters is lost. This will mean a difference of from one-eighth to one-half inch in the engagement diameters of the head. From two to four weeks earlier delivery in such cases would secure engagement and consequent reduction by molding.

Further let us note that, in weighing the evils of induction against forceps, it is not only a question of comparative mortality of the children but morbidity from the use of the forceps. It is strange how little attention has been given this subject. Injuries which must cause permanent damage are: Depression of bones, fracture of bones, fracture and compression of the brain, rupture of vessels in the brain or meninges and paralysis and fatty degeneration of the facial nerve. As to the relative danger to the mothers in induced labor and dystocia delivery, they are, no doubt, greater in the latter than in the former.

Finally, as a detail in the induction of labor, I venture to suggest, that, in my opinion, the best means of excitation are: (1) The sterile, solid, flexible bougie—which should be tapering and not blunt, to more surely avoid puncturing the amnion; (2) the small Barnes bag, used very slowly to excitation of pains only, and (3) the tampon, any of these to be preceded by the administration of a full dose of castor-oil.

THE TREATMENT OF TUMORS COMPLICATING PREGNANCY.[1]

BY BROOKS H. WELLS, M.D.,
OF NEW YORK;
ADJUNCT PROFESSOR OF GYNECOLOGY AT THE NEW YORK POLYCLINIC; FELLOW OF THE NEW YORK OBSTETRICAL SOCIETY; OF THE NEW YORK ACADEMY OF MEDICINE, ETC.,

THIS present paper is limited to a brief consideration of the dangers incident to the complication of pregnancy by various new growths involving the uterus or pelvis, and to the methods by which these complications can be best treated. The limited time allotted necessitates the omission of statistical data and references to the literature and confines the remarks to the most practical points.

Cancer.—In the early stages of cancer impregnation frequently occurs, and, while abortion is frequent, two-thirds of the cases go on toward term. The cancer, under the stimulus of the increased circulation and succulence of the tissues incident to pregnancy, grows and spreads with extreme luxuriance and the cachexia increases rapidly. Some of the women die before term

[1] Read before Section on Obstetrics and Gynecology of the New York Academy of Medicine, April 26, 1900.

from exhaustion or from a septic infection from the breaking-down cancer tissue, an infection which may be the result of bruising incident to even repeated digital examination. If they abort, there is increased risk from sepsis and hemorrhage. If labor at term occurs, over 30 per cent. succumb when delivery takes place spontaneously, many of these from rupture of the uterus, while about 50 per cent. die where the aid of forceps or version or craniotomy has increased the traumatism and subsequent exhaustion, hemorrhage, sloughing and sepsis. About 40 per cent. of the children are born dead and nearly all are of feeble vitality. This certainly is a gloomy picture, but it is not exaggerated and it warrants us in employing the most radical measures if by so doing we can lessen the immediate danger to the mother. A child soon to be motherless and of the most problematical vitality deserves only secondary consideration.

Treatment.—In the presence of cancer of the cervix it is usually impossible to be certain of pregnancy before the end of the third month. Here the child should be entirely ignored, for the operative indication is even more urgent than in the unimpregnated condition. While the uterus is yet small, it and the upper vagina should be removed by vaginal hysterectomy or by Werder's operation. When the conditions are favorable the vaginal operation is best. It should be begun by a circular incision of the vagina 4—6 cm. below the cervix, the vaginal walls being dissected off so as to form a cuff about the cervix, and clamped together by a stout pair of forceps, as suggested by Goffe, so as to shut off the cervix and its infectious material. The operation is then finished in the usual manner.

When the disease is more advanced or the body of the uterus is larger, Werder's method is advisable. Here the ovarian and uterine arteries are tied through an abdominal incision and the uterus freed from bladder and broad ligament without cutting through the vaginal wall. The vagina is then freed from its attachments by blunt dissection as far down as is thought advisable, and the uterus drawn down and out through the vulva by stout traction-forceps attached to the cervix. The peritoneum is then united over the fundus, the abdominal wound closed, and the operation completed by removing the uterus after dividing the inverted vagina at the point selected. If the uterus is too large to pass easily through the vagina in this way, a supravaginal amputation should be made to lessen its bulk before the removal below of the cervix and vagina. This method is ideal, in that it avoids any contamination of the peritoneal cavity or of any cut surface by septic or cancerous matter.

When the condition is discovered during the fourth or fifth month of pregnancy, immediate combined hysterectomy is still the procedure of choice. During the sixth month and later the viability of the child must be considered and the question of waiting until this is assured comes up. When the child is viable, induced labor and hysterectomy or Cæsarean section and removal of the uterus and vagina should be done.

When the case is first seen at term we may find cancer at so early a period that its diagnosis is uncertain. At this stage it does not prevent dilatation of the cervix, but predisposes to deep tears. When the disease is more advanced, but still combined to one lip, it may be scraped and cut away and dilatation aided by multiple incisions and rupture of the membranes so that the pressure of the head may aid in controlling the bleeding which, however, is not usually alarming. Where the cervix is extensively involved or where the cancerous masses are large, Cæsarean section and immediate removal of uterus and vagina is indicated. In these instances craniotomy on a living child is not justifiable, as the mother is doomed in any case, and the crushing and tearing incident to forcible delivery will probably hasten her death more than the abdominal section.

Where cancer affects the vulva, vagina or rectum, remove the mass, if small, and deliver per vaginam; but if the disease is advanced, the abdominal incision gives the best results.

Fibromata.—In the presence of uterine fibroids the chance of pregnancy certainly seems to be lessened, and when the woman is pregnant the risk of abortion is increased. Abortion in these cases is particularly dangerous from hemorrhage and sepsis.

It is certain that fibroids grow very rapidly when stimulated by the increased blood-supply incident to pregnancy, that they show an increased liability to inflammation and to cystic degeneration, often become very soft and succulent; on the other hand, they also quite frequently shrink rapidly or disappear during the puerperal period. This sudden augmentation in size, especially when the growth occupies the upper part of the cervix, rapidly increases any pressure symptoms that may have been present before impregnation.

Interstitial tumors, whether single or multiple, grow most rapidly, particularly in cases where the uterine wall is much thickened. Subperitoneal tumors, especially pedunculated, if near the fundus, do not grow as rapidly and are not as important in their effect on labor unless when very large. With submucous tumors of the body of the uterus, pregnancy rarely occurs and practically always ends in abortion. In general, the higher the situation of the tumor and the more it approaches the subperitoneal type, the less the danger: the most serious cases are those in which the fibroid occupies the pelvic cavity.

The presence of a fibroid is a cause for inefficient or irregular uterine contractions, and as the proper uterine reaction is interfered with, postpartum and puerperal hemorrhages become a serious danger. The condition predisposes to a vicious insertion of the placenta and to malpresentations of the fetus. Uterine rupture is not uncommon, being favored by the obstruction offered by the tumor and by the degenerative changes in the uterine wall caused by the pres-

ence of the fibroid. Inflammation and sloughing of the tumor from the pressure and bruising to which it is subjected during labor is very common and brings with it a most grave risk from sepsis. Excluding subperitoneal tumors of the fundus, the maternal mortality in labor complicated by fibroids has been in the past over 50 per cent., and the mortality to the fetus nearly as much.

Treatment Before Labor.—With small subperitoneal tumors of the fundus and a pregnancy well advanced, expectant treatment is allowable, but during the early months of gestation myomectomy is indicated and can often be done without interrupting the pregnancy. Where the tumor is at the lower uterine pole, enucleation per vaginam is best, as a waiting plan exposes the patient to great risks. With interstitial tumors of the body of the uterus, supravaginal hysterectomy is better than either abortion or premature labor and is easy because of the relaxation of the broad ligaments caused by the pregnancy.

During Labor.—With fundal tumors it is only necessary to be ready to secure contraction during the third stage. If postpartum hemorrhage occurs, explore the cavity of the uterus with the hand, as sometimes fibroids are found that can be easily enucleated, and then pack with gauze. Give ergot. Inversion occasionally follows delivery with tumor of the fundus and necessitates immediate enucleation and replacement, or if this is impossible, perform a hysterectomy.

If the fibroid obstructs labor and is in the anterior wall, it may sometimes be pushed out of the way with the patient in the knee-chest position, or it may be drawn above the brim by the uterine contractions. This cannot happen if the tumor is lateral or posterior. Tumors of the cervix must be enucleated when possible, as even when very small enucleation is less dangerous than forcible delivery. Fibroid polyps, detected only after labor, should be removed, as they are apt to slough and cause sepsis. If the fibroid obstructs labor and cannot be gotten out of the way it is nearly always better to do a radical abdominal operation than to run the very grave risks of sloughing and sepsis which so often follow forcible delivery by forceps or version.

To be successful these operations must be done early, and not late when the patient is exhausted, bruised and septic. If any sign of inflammation or sloughing appears after labor it must always be regarded as an absolute indication for removal of the tumor.

Ovarian Tumors.—Cysts or solid tumors of the ovary form a rare complication of pregnancy and labor. Small tumors, especially dermoids, are most dangerous, as they are most likely to become impacted in the pelvis. Large cysts are not likely to block the pelvis, but they produce great discomfort from pressure and are particularly liable to rotation and twisting or even tearing-off of their pedicles. The dangers incident to delivery by forceps, version or puncture from twisted pedicle, rupture of cyst, intracystic bleeding, suppuration of cyst-contents, intestinal occlusion, septic infection and peritonitis, are so great that the records show a mortality of nearly 50 per cent.

Treatment.—When seen early in pregnancy there is no doubt but that an abdominal section, preferably by an intermuscular incision similar to that now employed in operations for appendicitis, with removal of the cyst, gives the best results. After the fifth month, if the cyst is not impacted and not large, it is right to wait till the fetus is surely viable before operating, but the patient must be kept under constant supervision. At term, if the cyst is small, the child may be driven past it by the natural efforts of the mother. At times the cyst may be pushed above the brim, the patient being anesthetized, if necessary, and put in the knee-chest position. If the cyst is not impacted and labor is progressing well, operation should be deferred until after the birth of the child. With an impacted cyst, puncture or incision through the vagina and delivery by version or forceps would seem the most natural thing to do, but the mortality is so great that it can very rarely be justified. Cæsarean section or supravaginal hysterectomy and removal of the cyst offer the greater chances of safety to both mother and child.

In addition to the three important classes of tumors that have just been discussed, labor may be obstructed by bony outgrowths over certain of the pelvic joints, enchondroma, cysts of the pelvis, hydatid cysts, sarcoma or cancerous infiltration, displaced kidney, and by the muscle-mass that sometimes results from ventral fixation of the uterus. In any of these conditions labor may terminate through the pelvic channel when the mass can be pushed aside or removed, but where the obstruction is serious, Cæsarean section by modern methods will save more lives than forcible dragging of the child through the pelvis. My experience is that during pregnancy abdominal operations in general are well borne and, because of the elasticity and succulence of the tissues, are not as difficult as would be supposed. When possible, see that the excretory organs are put in the best possible condition, avoid all unnecessary hemorrhage, and, particularly, use the most rigid precautions against any septic infection.

71 West 45th Street.

THE INDICATIONS FOR PREMATURE DELIVERY, WITH SPECIAL REFERENCE TO ECLAMPSIA AND THE PRE-ECLAMPTIC STATE.[1]

By S. MARX, M.D.,
OF NEW YORK;
ATTENDING SURGEON TO THE NEW YORK MATERNITY.

In discussing the subject of the indications for premature delivery, I shall dwell particularly on those offered by the toxemia of pregnancy as well as those indications induced by a disproportion

[1] Read before the Section on Obstetrics and Gynecology of the New York Academy of Medicine, April 26, 1900.

between the fetal head and the maternal pelvis. All other indications, and many there are, will simply be mentioned in passing, and for the reason that, while in the latter, for instance, cases of placenta previa and the malignant forms of vomiting of pregnancy, the indications for the interruption of the gestation are well defined and fairly well understood by all practitioners, yet for the former, eclampsia or the pre-eclamptic states, and the subject of pelvic distortion or contraction, relative or absolute, there is such a mist of doubt surrounding the whole question, that many hardly understand the subject at all. On the other hand, there are those who are so confused by the varied and alternating views of our teachers and leaders that they are really at a loss to recognize a means for the induction of premature labor in the conditions just mentioned.

I have always maintained that success in midwifery is not attained by skill in operating. Far better is he, the skilled accoucheur, who can place the indications; for when the indication is well placed, the operation becomes a secondary consideration. An operation, the indication for which is false, can only end in disaster, no matter how skilfully done; on the other hand, clear and concise indications, for no matter what form of obstetric operating, are always followed by good results. The one depends upon the other. In placenta previa, central or partial, or situated dangerously near the dilating zone of the uterus, even though this vicious situation of the placenta is not within reach of the examining finger, and therefore only strongly suspected, there is an almost universal tendency among modern obstetricians to empty such a uterus at once. Until this is done, the woman as well as the fetus is in constant danger from severe and exhausting, if not fatal, hemorrhage. I could go on mentioning such indications by the score, but since there is hardly a difference of opinion in these clear cases, we have but little to discuss.

How different is the condition in eclampsia, or what is a preferable term, the toxemia of pregnancy. At once this confusion of names makes the subject difficult, for we recognize the fact that we are fighting a pathologic state whose vicious complex of etiology and diagnosis is difficult to penetrate. Were there unanimity of opinion, we would feel right in our deductions, even although absolutely wrong, for we know no better. We are no nearer the solution of this problem of uremia or urinary toxemia to-day than we were years ago. All that we can state to-day, and modern scientific investigations do not allow us to state more, is that the system is influenced by some unknown toxic material, arising in the body *per se*, thus constituting an autotoxemia. Whether such depends on the liver, the intestinal tract, the fetus or the kidneys, one or all, is the unknown element and the great stumbling-block. On the other hand, there is the possibility of it being a disease of the heterogenetic infective type, having a bacillary origin with its bacterial toxins. Theoretic reasoning is good and nice as far as it goes, but at the bedside of a woman threatened with so dangerous a complication, we want facts to guide us and treatment to help us. Clinical experience is our best teacher, and this shows us that eclampsia is closely allied to, and largely associated with, kidney inadequacy, and the surest method of treatment is the rapid return of diuresis.

This leads us up to the question when this condition obtains, how long may we procrastinate and treat medically? We are told that when medicines fail, surgery steps in. When are we to know when to interfere? Is it when the woman is already in the throes of a convulsion with its appalling death-rate? Can we predict when the first convulsion is to occur, or, when it occurs, do we know that it will not terminate fatally? Our treatment must be early and timely. I cannot understand the position taken by French surgeons, who, even in the face of convulsions, advise temporizing, for the fear of inciting more violent or more frequent spasms by such active interference. If their results following this waiting policy are in accord with ours, how awful must be the death-rate!

In the study of the pre-eclamptic period, we recognize two conditions which are the direct causal factors in producing it. The first, the true, frank complicating albuminurias, or the exacerbations of an antecedent condition; the second is little recognized because of the complexity of its etiology, and the supposed difficulty of diagnosis. It is a condition in which there appear none of the characteristics of a true acute (parenchymatous) nephritis of pregnancy, but nevertheless in the unrecognized case carries with it a prognosis which is very bad, but just the reverse when timely treatment and interference are instituted. It is variously denominated by the terms, uremia, urinemia, or the true toxemia of pregnancy. In the first class of cases, we have the prominent symptoms clearly defined by urinary examinations. This calls our attention to the fact that close chemical analyses must follow in order to clear up in our minds what is the sole dominant pathologic entity which produces the constitutional symptoms. In addition to the albumin and the casts we turn our attention to the amount of urea excreted and upon its diminution and increase will depend absolutely our further course of treatment. That urea is the agent that is provocative of eclampsia is to my mind proven beyond a doubt. Clinically, by the increased toxicity of the blood of the patient and the diminished virulency of the patient's urine. In personal practical experience, in a large number of women in whom a toxemia was not present, even although albumin was found in large amounts in the urine, 5 per cent. of all pregnant women have an albuminuria. I have seen a great many women with all the urinary symptoms of an acute or chronic nephritis, but have *never* been compelled to induce labor, nor have imminent uremic symptoms ever occurred as long as the urea has been excreted in normal amount. By a

normal amount of urea, I mean the estimation from a sample of the total urine; in round figures, about 500 grains per day, in women otherwise healthy. For it must be remembered that underfed patients, such as we see at the hospital, persistently excrete a smaller amount of urea without symptoms. Further, it must be borne in mind that persistent vomiting, such as occurs occasionally in pregnancy, will markedly diminish the urea excretion, and is dependent upon it, not, as we have been told, that the excessive vomit depends upon the diminished urea.

Urea is the chief product of the body oxidation of albuminoids and the amount thrown off indicates the amount of disintegration of nitrogenous material. What is of greater importance is the fact that in a number of cases, most of them fatal, is that class in which the most careful examination is negative so far as albumin and casts are concerned. Such are cases in which violent convulsion occur, always preceded by classic symptoms of a true uremia. In them the only suspicious condition is the marked diminution of urea. It is this urea that kills, not the albuminuria. If we can only impress this fact upon all medical men, that the estimation of urea is of far greater importance than the presence of albumin, our position will become of some worth. A special emphasis is laid upon the fact that in the majority of albuminurias we simply have a day's signal as a warning of an impending catastrophe. On the other hand, the absence of albumin means absolutely nothing in the presence of certain symptoms. We wish to go on record as stating that the induction of premature labor is never countenanced by the mere presence of albumin in large or small amounts and casts, but always strongly advise the prompt emptying of the uterus in all cases in which scientific medical treatment fails and the urine shows a progressive diminution of urea.

To recapitulate: (1) Toxemia of pregnancy is a complex condition depending on more than one factor. (2) Many women go to term with albuminuria without symptoms referable to toxemia. When such symptoms arise, they are not caused by the albumin present, but faulty urea excretion is always found. (3) In the most desperate and malignant cases there is found neither albumin nor casts. (4) Urea is always found markedly diminished in these so-called true toxemias of pregnancy, or urinemias. (5) Finally, we make a strong plea for a regular and methodical course of urea estimation in all cases instead of, or relegating to secondary importance, the time-honored examination for albumin. (6) Progressive diminution of urea excretion with or without albuminuria is our sole indication for the induction of premature labor which is especially indicated when conscientious medical treatment fails.

The next topic to be considered is the indication for the induction of premature labor for disproportion between the fetal head and the maternal pelvis. It will be noted that I ignore absolutely the term "contracted pelvis," as the title for the second division of the article. This is done purposely, for my experience with many so-called contracted pelves has made me an almost utter skeptic as to its frequency and makes me feel that a true contracted pelvis is a rare condition. The only true contracted pelvis that I *do* admit is one which will not admit the passage of any child, living or dead, entire or totally dismembered. In all other cases, it resolves itself into a question of disproportion between the head and pelvis, *i.e.*, between passenger and passageway. What is a normal pelvis? The answer is a frank one. I do not know. We can never measure a pelvis, we can only estimate its diameters. Very few pelves are absolutely contracted; all may be relatively so. Given a certain pelvis the diameters of which we have carefully estimated, in one labor everything goes smoothly because the head is of average size and well posed; in the same pelvis, a year or two later, the most difficult form of operating may become necessary because of the large head. This I realize is an extreme case, but have we not all met such? Such disproportion will give the accoucheur more to think about and more worry than is likely to occur in labors with the pelvis one or two inches smaller all around with a small fetus as a passenger. It is and always has been the size of a particular head passing through a particular pelvis which has caused the dystocia, and in the largest number of cases the sole cause of a supposed pelvic contraction. We do not measure the pelvis by inches, centimeters or millimeters, as our learned friends in other cities do, but we gauge its receptivity and capacity; no matter how narrow a pelvis may be revealed to us by the pelvimeter, it is never so small but that a child may be born through it either naturally or by minor operative measures; this, of course, always depending on the size of the child. I feel that such a statement will stir up a hornet's nest, but it is made advisedly. To go into details by quoting case after case to prove these assertions, is foreign to my mind, but generally speaking, I will say that I *have seen babies born naturally by women about to be subjected to either Cesarian section or symphysiotomy.* Such babies are, of course, small. I recall one case of face presentation which was born through a pelvis whose diameter would have justified this form of operating with a large baby. On the other hand, we have met many cases where pelvic estimations would make us apprehensive; and yet, by measures to be explained below, we deliberately allow the woman to go to term, and rarely has temporizing been ill advised.

What, then, is our indication for the induction of premature labors in these cases? Are we to be hampered by adhering to the old-fashioned tables found in nearly all our text-books, which tell us in a dictatorial fashion that when the pelvis is contracted so and so much, induce labor at the twentieth, thirty-sixth or thirty-eighth week? Are we to be so blindly scientific, and to lose that

which we all ought to possess, namely, common sense? Is the book-worm scientist better off if he tells a young mother that, because she has a pelvic contraction to 10 cm., her labors must be induced at the thirty-second week? Possibly, but I doubt it. But suppose this young mother goes to another less brilliant practitioner. He laughs it off and tells her, in his inexperience, she is all right—and she is all right, for she goes to term and is delivered naturally of a small baby. Does the young mother know the small baby was her good fortune? She wanted her baby naturally; she got it. The scientific accoucheur got what? The black eye. And the pseudo-one obtained the reputation. Except in absolute pelvic contractions, we never elect the induction of premature labors until the time comes for its performance, and that time arrives when we cannot get the head to engage by suprapubic pressure. Our mode of procedure is as follows: Every woman at her first visit is subjected to a thorough pelvimetric examination, not that we are absolute believers in the pelvimeter, but because this instrument gives us a clew to pelvic distortions and contractions. When nothing suspicious is found, the probability is that the labor will be normal, providing the fetus is not too large or malposed; and yet, to avoid this, the woman is subjected, from the eighth month, to the same manipulation as one with a small pelvis, in whom the examinations commence at the seventh month. From this time on, once in two weeks, the gravid woman is examined in the bed. With well-flexed legs, the bladder and rectum being empty, one or two fingers of one hand are introduced into the vagina, while the disengaged hand grasps the head which lies in or upon the brim. By firmly pressing it into the pelvis in the line of the axis of the superior strait, downward and backward, the head is made to enter the pelvis. When this is found just possible, then the head is certainly not capable of entering that pelvis at a later time; or, if we find the head and pelvis fit snugly, the same indication holds good, and that is the time to induce labor. But if, in spite of even a considerable pelvic contraction, we are able by our suprapubic pressure to get the head to engage up to the end of a normal uterogestation, we find no indication for interference. For we are of the belief that a head that will engage at the brim will readily pass through the pelvis, for funnel-shaped pelves are so extremely rare as hardly to be considered.

We have attempted in this paper to make ourselves clear as to the following points: (1) That the term pelvic contraction is only a relative condition: and in but a very few cases does the bony pelvis afford an absolute indication and that in cases only where neither a living nor a dead child can be delivered by the natural passages. (2) We do not measure a pelvis by inches, centimeters or millimeters. We estimate its size and test its capacity for the reception of the head which must pass through it. (3) Small and even fair-sized fetuses have been delivered through pelves whose diameters were far from normal and in which the possibility of major forms of operating were to be anticipated; and in some major operative interference had already been in active process. (4) Women with apparently normal pelves in labors with large children very frequently give us the picture of a pelvis relatively contracted, and as such would warrant operations of a more difficult type than those in whom the pelvis shows a diminution in all its diameters. (5) We advise against the election of any form of operating months before, since the fetal head must always remain the sole doubtful element. (6) When once we fail to get the head to engage, it is proof positive that the pelvis is too small for the head, or the head too large, and when this condition obtains, the time to interfere is at hand. (7) We advocate the systematic use of the pelvimeter for purposes of comparison only. We deprecate the absolute value of the instrument as one of precision, and never pin our faith as to results which it gives in determining when or when not to induce labor when there is disproportion between maternal pelvis and the fetal head.

947 Madison Avenue.

WHEN IS IT PROPER TO INTERFERE IN APPARENTLY DIFFICULT OR DELAYED CASES OF LABOR, ESPECIALLY IN PRIMIPARAE.

BY MALCOLM McLEAN, M.D.,
OF NEW YORK.

THE prevention of evil is generally more satisfactory than striving to overcome its deplorable consequences. And in medicine it is the ideal which we should keep before us. In no branch of medicine, perhaps, have we more frequent opportunities for exercising our skill in the prevention of unfortunate conditions than in obstetrics. The above subject of discussion illustrates forcibly the importance of a careful consideration of the subject from different standpoints.

The process of parturition is ever with us; and, although so-called civilization has succeeded in part in modifying the laws of maternity to a considerable degree, still maternity is an essential factor in the growth and maintenance of the great human family. It is not—or ought not to be—a pathological process, but a physiological one. When disease interrupts or disturbs it, when mechanical difficulties prevent or obstruct it; when injury to mother or child results from its performance, it becomes a pathological one. When a healthy living child is born, leaving a mother with uninjured tissues to complete later processes of involution according to Nature's plans, we have the picture of a physiological parturition, which should be the model up to which we would endeavor to bring our obstetrical work.

Much has been well said and written concerning the various accidental or incidental causes of departure from the normal type; and we cannot pay too much respect to the important teachings

so clearly laid down. It has occurred to the reader that he can possibly contribute, if not a new thought, at least a new emphasis to a thought in offering a few words as to the *time* which should be allowed to elapse before we, as obstetric attendants, may with propriety interfere in assisting the parturient act. And, in order not to waste valuable time by repetition of directions suggested by others, as in case of disease, deformity, malposition and the like, it is intended to confine these very meager suggestions chiefly, if not entirely, to one source of untoward consequences, occurring in primiparæ in particular.

A reasonably careful consideration of the injuries inflicted in childbirth will convince one at once that by far the saddest and most serious are inflicted upon the mother in childbed for the first time. Thousands of otherwise healthy, robust and happy young women are annually plunged into the miseries of invalidism, and many are sent to an untimely grave by this function—the highest of her nature—one which, we must admit, should be classed among the functions which we recognize as physiological. The frequency of this awful change, which so suddenly transforms a happy life, is itself sufficient to demand our earnest observation and study of the facts. If it be true, as we have premised, that this sudden transition from health to disease, from happiness to misery, from life to death, comes so frequently and particularly to primiparæ, then it points certainly to a fact—there must be an element of danger in the primipara, which is frequently absent in the multipara; and of this we should take careful heed.

The fact that malpresentations and malpositions of the child, that diseases and deformities of the mother may obtain in the case of the multipara, as in the primipara, does not in any way detract from the force of the proposition before us, namely, that a woman bearing her first child is, for reasons peculiar to her class, particularly liable to certain difficulties and dangers, which seldom menace the woman who has before gone through the normal stages of labor.

In order to keep this argument within the briefest possible lines, consistent with intelligibility and scientific value, let us note that, inasmuch as there is practically no difference between the first child and the third, or fifth, the difference must exist in the mother herself. And, as the forces are about the same in the one class as in the other, it must have to do with the passage through which in each instance the child has to travel.

Having thus sifted the matter down to this point, we may readily throw out of consideration the parts which remain practically immutable in each, multipara and primipara, the bony canal of the pelvis, since this is no more a factor in the one class than in the other. We have, therefore, the soft structures of the mother alone to consider.

What is the difference between the tissues of the young mother, with her first child in transit, and those of her who has already experienced the function of childbearing? Simply that in the primiparæ that peculiar, physiological softening down and relaxation of the soft parts, which should precede the passage of the child, goes on generally very slowly, occupying many more hours in its accomplishment than in the case of the multipara. Hence, if this metamorphosis, or physiological change, be not permitted to reach its proper accomplishment, and surgical interference be offered before the tissues shall have made the necessary change, then, injury is bound to follow with all its direful consequences.

It is to this oft-repeated error of truly "meddlesome midwifery" that the reader desires to point with distinctness and emphasis. The question of long-continued pressure, with its dangers, must not cloud the judgment. We all know, or ought to know, the indications to assist an arrested head which is threatening the vitality of the maternal tissues. But too many of us are apt to forget that there is another extreme to which we should not go, if we would let Nature do her normal work with our assistance. We have seen obstetricians smile incredulously at the importance given to the changes in maternal tissues above alluded to; and we have known them to explain the tardiness and difficulty of the case by assuming and asserting the existence of "slight pelvic contraction," etc. But when a second confinement in the same woman was experienced, we have noted that the "pelvic contraction" was not involving the case.

We believe that obstetricians should remember and that patients should be taught to understand that there is something more in the complex process of childbirth than the mere change of location of the child from the womb within to the world without. There is a clearly-marked process of preparation, through the circulatory forces in the tissues involved, which causes relaxation and stretching of muscular expansions and absolute softening of mucous and other structures, thereby fitting them essentially for the extraordinary distention to which they are to be subjected. If, before such changes have taken place, operative interference be precipitated, the structures are liable to extensive and dangerous lesions with all the ills attending such accidents. It is pretty desirable, then, to take careful account of all the conditions obtaining in a given case before we decide to intervene with surgical assistance. If the presenting part be high up and movable, the pelvic measurements within normal limits, the soft parts unrelaxed, not edematous or swollen, the case may be and should be allowed to proceed without interference. When the forces are apparently normal, the presenting part arrested at any given point, say, for over half an hour, or, if the soft parts of the mother, having once been relaxed, thoroughly moistened with mucus, are becoming hot, edematous and discolored, the indications are clear for early and efficient assistance. When these indications appear there should be no delay.

29 East 126th Street.

DISCUSSION ON SYMPOSIUM.

Comparative Prognosis.—Dr. E. A. Tucker opened the discussion. He said that the prognosis of what will happen in a second labor from the course of the first labor is by no means absolute. The first labor gives valuable hints, but not positive indications as to the conditions that will obtain in succeeding labors. Experienced obstetricians know well that labors in the same woman may be very different, although the child and the presentation may not differ from those of preceding labors. The nervous condition of the woman, her general health, her muscular tone—in a word, her constitutional condition has a great deal of influence on the character of a particular childbirth. This makes the value of pelvimetry very relative. Medical literature is full of laudation for the preliminary information that may be gained by pelvic measurements. Much of this except in extreme cases is a delusion. The text-books have given entirely too much weight to this aspect of advance in obstetrics. A good-sized pelvis and a not abnormally large child may yet give rise to difficulties in a labor which will be extremely annoying and require most skilful interference. The induction of labor, especially in the better classes, is an expedient that will surely find more and more favor with obstetricians as time goes on. There is a slight increase of infant mortality, due to it, but this is not enough to dissuade from the employment of a method which often saves maternal life and always lessens maternal danger. The time when interference to produce labor is advisable is a most difficult problem to decide. Of late we have learned that we can by combined manipulations decide whether the head seems growing too large for engagement at the superior strait. The employment of some such method will be undoubtedly the duty of the obstetrician in the near future.

It is the amount of urea that a woman is passing and not the amount of albumin that constitute the danger-signal for the development of eclampsia. In every suspicious case, that is, in every pregnant woman in whom there is some headache and restlessness for which no good reason can be found, and especially where edema or eye-symptoms develop, a careful estimation of the urea that is being excreted in the urine should be made. This is the imperative duty of the obstetrician. For the ordinary healthy woman without these symptoms, this careful investigation of the urine is not needed. But the slightest suspicion should be sufficient to ask for a sample of the urine and not be satisfied merely with finding out whether or not it contains albumin. The presence or absence of albumin may under circumstances be a very fallacious criterion.

Walking During Pregnancy.—Dr. Tucker recommends pregnant patients to walk a good deal during the latter months of their pregnancy. He considers this the very best form of exercise for them and one that is well calculated to favor the engagement of the fetal head. The walking should be increased more and more toward the end of the pregnancy. If at the end of eight-and-a-half months the head is not engaged the daily walk should be increased one-half mile each day, until the patient is walking at least six miles. Another exercise that is of great service is for the woman to lie in bed and lift herself up to a sitting position without support. This brings into play her abdominal muscles. It increases their functional capacity, makes them of more service during the actual labor itself and presses the head well down into the pelvis before labor begins. The old adage, "let Nature take her course," is a very good one under proper circumstances, but it has killed many an obstetrical patient. There are two classes of physicians who make mistakes in the treatment of obstetric cases. They are the extremists, the non-interferers who wait too long and the meddlers who are in a hurry to help Nature along. Both of them entail unnecessary danger on their patients.

Pelvimetry.—Dr. Egbert H. Grandin said that he is a thorough believer in pelvimetry. It would be better for patients if there were more of it. The result of an obstetric case, however, is never a question of millimeters, nor of quarter- or half-inches, but short diameters discovered by the pelvimeter arouse suspicion and so lead to the taking of precautions which save annoying delay and the development of serious conditions. A woman with an average normal pelvis may yet have considerable difficulty in labor. She will have much more difficulty in one labor than in another, depending on the relation of the child to the pelvic canal and on the strength of the expulsory forces. Besides pelvimetry of late years, we have learned that we can find out whether the fetal part that presents will engage or not. If the presenting part will engage under suprapubic pressure, then the woman will deliver herself without difficulty, as a rule, or at least without insuperable difficulty. The difficulties encountered from a narrow outlet in a funnel-shaped pelvis are so rare that they may practically be neglected. If, however, the presenting part cannot be made to engage, it is an indication that active interference will be necessary. For this the induction of premature labor, when not too soon before the expected normal birth, is a very useful procedure. Dr. Grandin is sorry that he cannot agree with Dr. Ayers that the introduction of a sterile bougie is an easy and effective way of inducing labor. Days and weeks even are needed sometimes before pains are initiated by this method. Besides, it involves imminent risk of the rupture of the membranes and the loss of the waters at the very beginning. This would completely spoil the natural method of dilatation for labor. Barnes' bags are also unreliable. The best method in Dr. Grandin's experience has been a preliminary tamponade of the cervical canal until the lower segment of the uterus becomes soft; then, manual dilatation with extraction ac-

companied by version, if necessary. Dr. Grandin has used this method in a number of cases now and has been very well satisfied with it. It causes no annoying delays for the patient or the physician and is less liable to cause complications, infective or otherwise, than any other method advised.

Toxemia of Pregnancy.—Dr. Grandin said that this subject is undoubtedly very poorly treated in the text-books on obstetrics. The older text-books advised a perfunctory examination of the urine for albumin as the important point. There are even some of the modern obstetrical manuals which give only the same advice. This doctrine should be relegated to the limbo of worn-out obstetrical traditions. Dr. Grandin has seen fifty per cent. by bulk of albumin in the urine and absolutely no trouble for the pregnant woman. On the other hand, he has seen not a trace of albumin present in cases in which uremia in its worst form developed. It often came on suddenly and was followed by coma and death before measures could be taken for its relief. Opium and pilocarpin and venesection have each had their day in the treatment of this toxemia. None of them has accomplished any good. Veratrum viride, employed up to the stage when the pulse dropped to fifty or sixty, was also ineffectual in preventing a fatal termination. The rule should be not to wait for cephalalgia, or such severe eye-symptoms as diplopia, but as soon as milder symptoms develop and persist and the excretion in urine is very much less than it should be and ordinary treatment fails to relieve these conditions, then the uterus should be emptied. After this the colon should be irrigated, venesection should be employed and nitroglycerin administered, if it seems indicated. When this is borne in mind and the old traditions of useless medication for the condition are forgotten, we shall have fewer deaths from the toxemia of pregnancy.

Dr. Barrett said that it is not the amount of albumin in the urine, but the deficiency of urea which causes toxemia in the pregnant woman. He has seen large amounts of albumin, yet the patient went on to safe delivery at term. On the other hand, absence of albumin gives no assurance of safety from toxemia. True contraction of the pelvis is rare. Very often in difficult labors where we believe that we have to do with a contraction of the bony pelvis, it is really the soft tissues which interfere with the normal progress of delivery. It is evident, then, that pelvimetry has only a relative value. It is a little like measuring the outside of a house in order to find out whether a man could pass through his bedroom-door. The future will surely demonstrate that the soft tissues have most to do with the interference with labor. The practical rule for the obstetrician is to wait as long as labor progresses, no matter how slowly it may be progressing. To interfere before progress stops is practically always unjustifiable.

Dr. Francis Stewart said that during the last months of pregnancy the urine of every patient should be examined carefully. The pelvimeter is fallacious and a practised sense of touch and an experienced judgment as to the relative sizes of fetus and pelvis are much more important and much better guides. Walking cannot be too much insisted on for the pregnant woman. During the latter months, especially when the disinclination to walk is very strong on the part of most women, the taking of long daily walks must be insisted on.

Dr. Ayers said that there must be some restriction as to the amount of walking in certain cases. Where the amount of urea excreted is a little lower than normal there is a narrow margin for the excretion of metabolic products. In these cases any excess in exercise might easily precipitate a serious uremic condition.

Restriction of Diet.—Dr. Marx said that in stout women, who are liable to have fat babies, the restriction of starches and sweets has always seemed to him a very good procedure. They should be advised to take frequent acidulated drinks and to eat plentifully of fruit. Not satisfied with this, some years ago in two cases in which he feared trouble because of overfat babies, he advised the use of thyroid gland. It was used very sparingly, beginning with a quarter of a grain three times a day. At no time did either of the patients take more than a couple of grains three times a day. Both of them complained that they felt life much less vigorously than before. And he feared that a continuation of the treatment might prove serious to the children. It was stopped. It is sad to think how often uremia occurs in physicians' wives. Too often physicians do not realize that albumin is of no importance and that it is the diminution of urea that causes the toxemia.

MEDICAL PROGRESS.

Scarlatina Antitoxin.—Having reported the discovery of the germ, the diplococcus scarlatinæ, and believing it to be the specific cause of scarlet fever, its presence being easily demonstrated in every case of the disease, W. J. Class (*Phila. Med. Jour.*, June 23, 1900) has made some experiments in an endeavor to find an antitoxin. It was difficult to get a culture which could be used as a standard, because of the fact that the germ varies so much in its virulency. A pure bouillon culture of the germ was finally obtained and filtered through a porcelain filter. A small injection of this killed mice within from twelve to thirty-six hours. A chemical examination of this toxin was not made and, therefore, its nature is not known. As it was known that swine were susceptible to the germ, the writer used a female, weighing about twenty-five pounds, in an endeavor to render it immune by administering successively-increased doses of the toxin. At intervals of about sixteen to eighteen days four injections of respectively 1 cc., 2 cc., 3 cc., and 5 cc. of this filtered culture were given to the animal.

The reaction following the injections diminished after the first two and was least after the last and largest, that of 5 cc. of the filtered culture, at which time the writer considered the animal to be relatively immune. The animal was then bled and the serum obtained from which some effect might possibly be expected. Mice were found too susceptible to the germ and too small, and white rats have a natural immunity, so guinea-pigs were selected for the experiments. A culture was now obtained of which 0.1 cc. in 1 cc. of water proved fatal to a guinea-pig if injected into the abdominal cavity. Four sets of experiments were made, two guinea-pigs being used for each experiment, one animal receiving an injection of the germ alone, while the other received the germ plus the serum. In Experiment 1 the guinea-pig, which received an injection of 0.1 cc. of the culture dissolved in 1 cc. of distilled water, quickly sickened and died. The other guinea-pig received a similar injection of the same strength and size, but it was preceded by a subcutaneous injection of 1 cc. of the serum. There was no reaction in this second animal, which has since remained well. In the organs of the guinea-pig which died the Diplococcus scarlatinæ was found. Experiment 2 (similar to Experiment 1) presented the same results. In Experiment 3 the animals were inoculated with a culture obtained from the liver of the guinea-pig which died in Experiment 1. The unprotected animal died within fifteen hours. The other animal received first an injection of .5 cc. of the serum, but it sickened and died within thirty-six hours. This culture was, however, more virulent and the dose of the serum smaller. In Experiment 4 the animals were treated in the same way as in Experiment 1 and with the same results, *i. e.*, the animal which received the serum lived, the other died. In all the animals which died the Diplococcus scarlatinæ was found in their livers, kidneys, spleens and heart's blood. The writer does not wish to claim that he has been able to produce an antitoxin that will do for scarlet fever what diphtheria antitoxin has done for diphtheria. He simply states the facts as he found them in his few experiments. He still believes that the Diplococcus scarlatinæ is the specific cause of the disease, and feels sure that others will arrive at the same conclusion if they will give the matter an unprejudiced investigation.

A Case of Pernicious Anemia with Yellow Bone-Marrow.—In most cases of pernicious anemia the yellow marrow of the diaphyses is converted into red. There is, however, another, the aplastic type, which differs from the first-mentioned, the metaplastic, in the entire absence of regenerative power on the part of the hematopoietic tissues, and thus no red marrow in the long bones forms. C. S. Engel (*Zeitschrft. f. klin. Med.*, Bd. 40, Hft. 1 and 2) relates a case with the following blood-analysis: Red cells, 2,115,000; hemaglobin, 18 per cent.; slight poikilocytosis; no microor macrocytes; no nucleated red cells; leucocytes much diminished; no eosinophiles; neutrophiles, 7 per cent.; lymphocytes, 90 per cent.; no myelocytes and no polychromatophilia. In the entire absence of marrow-elements the blood lacked the pathognomonic cells of metaplastic pernicious anemia. The author discusses the question as to whether his case can be included among the aplastic type and whether it is possible to ascertain from the condition of the blood the state of the blood-forming organs. Normally the marrow is the most important source of both red and white cells, the spleen and lymph-nodes being of importance only in relation to lymphocytes. In case the marrow has lost its function, the nucleated cells from which the normal erythrocytes develop will disappear, the erythrocytes themselves will diminish, neutrophile leucocytes will become scant, while lymphocytes will be present in abundance, since their source of origin is intact. The post-mortem examination of the author's case showed the anticipated absence of red marrow and many non-motile bacteria, the character of which was not determined, in the marrow of the ribs.

Prolonged Sleep.—A unique case of prolonged sleep of seven months' duration in a girl eighteen years of age, suffering from sarcoma of the pituitary body, came under the care of F. Soca (*Gaz. hebd. de med. et de chirurg.*, May 31, 1900). There was at first general asthenia with headache, optic atrophy, especially on the left side, with dilated pupils not reacting to light, but no ocular palsies. Soon the sleep began, from which the patient only awoke to take food. Toward the close of the disease, memory and attention were much affected while the patient was conscious; speech was incomprehensible, the reflexes were exaggerated and there was some muscular atrophy. Death resulted from bronchopneumonia. A tumor the size of a mandarin, reaching into the third ventricle, was disclosed on autopsy.

Chronic Purulent Otorrhea.—A suppuration of the middle ear not kept up by necrosis, polyps or a foreign body, is usually chronic because (1) the tissues are lowered in vitality, (2) the septic material is active, and (3) drainage is poor. The necessity of pursuing active treatment in these cases is urged by C. L. Filt in the *New York Medical Journal* (June 23, 1900). The drainage can seldom be improved, but the tissues may be stimulated and the virulence of the germs destroyed. When the discharge is profuse the ear should be syringed out two or three times a day with a very warm solution of two-per-cent. carbolic acid or other antiseptic. Once a day after irrigation, the canal should be mopped out with absorbent cotten and an antiseptic dusting powder be blown in. Too much powder should not be used to block up the canal. This "dry treatment" will cure a case in one-sixth the time required by solutions. The best powders to be used are the iodine bearing ones, such as iodoform, iodol, aristol or iodomuth. When the dis-

charge is slight irrigations need not be used, but the insufflations should be employed once a day.

The Value of the Tuberculin Test.—The value of the tuberculin test in the early diagnosis of cases of tuberculosis is discussed by J. M. Anders in the *New York Medical Journal* (June 23, 1900). It does not depend on its greater reliability as compared with other methods, but rather upon the fact that it permits of the recognition of the disease in its latent as well as in its incipient stages. M. Beck reports that out of 2508 injections made, tuberculosis was first detected in 1154 cases by means of the reaction obtained. It is claimed that a well-defined reaction occurs in eight-per-cent. of apparently healthy individuals, yet some of these may be latent or obscure cases. Failure of reaction in dubious cases is often due to the fact that too small a dose has been given. Cases of bone and joint tuberculosis require larger quantities than any other form of the complaint. It is believed that medium-sized initial doses (from two to five milligrams) should be employed since this usually obviates the necessity of repeated injections. The results of a large number of investigators show that the test is sufficiently accurate for practical purposes. It has been claimed by Virchow that tuberculin caused a maceration and softening of the tubercles which might result in the liberation of the bacilli from tubercles in the process of recovery. More subsequent clinical investigations have led nearly all competent observers to emphasize its superior value as an aid to diagnosis and to confirm the claim of apparent harmlessness. Since tuberculin does not aid the healing of diseased areas it should not be used when the diagnosis is clear. Furthermore, the more extensive the lesion, the larger the dose required to obtain a reaction, and the greater are the ensuing local disturbances.

Ceruminous Impactions in External Auditory Canal.—To the general practitioner a few very useful hints are given by S. Kohn in the *Medical Record* (June 23, 1900) in regard to the impactions which occur in the external ear. About fifteen per cent. of all cases of ear disease are due to this affection. There are three varieties, the classification depending upon the composition of the plugs. The simple ceruminous impactions, sometimes containing a nucleus and consisting also of epithelial cells, hairs and detritus, are the most frequent. A second variety is the epithelial plug, found principally of epithelial scales and is due to a chronic desquamative dermatitis. The third variety is the cholesteatoma of the external canal showing through the speculum as a pearly gray mass. It usually originates in the mastoid cells and by absorption works its way to the canal. It is claimed by some that every case results from an inflammation of some part of the auditory apparatus stimulating the secretion of cerumen. As a rule, after the removal of the plug there is not the complete restoration of hearing that is usually expected, for there is often an old otitis media or disturbance of the function of the membrane or ossicles due to the pressure of the plug. The head-mirror and speculum are all the instruments necessary to make a diagnosis. A patient complaining of deafness coming on suddenly, fulness of ear, dizziness, who hears the tuning-fork applied to the middle of the forehead more markedly on the deaf side than on the normal, has probably an occluding plug. The best method of treatment is the use of large quantities of sterile warm water. The water should be at about 80° F. and unmixed with anything except perhaps bichloride, 1:5000. A large sterilized syringe is used and about a pint of water carefully injected into the ear. If the plug is very hard a saturated solution of bicarbonate of sodium or a two-per-cent. solution of carbonate of potassium in equal parts of glycerin and water may be dropped into the ear three or four times per day. Two days of such treatment are usually sufficient. Cases requiring the curette, forceps and probe had better be left to the specialist.

Appendicular Pleurisy.—The following are the conclusions of M. Dieulafoy (*Bull. de l'Academie de Med., La Revue Méd.*, p. 365) on this subject: This is a distinct disease and, just as hepatic abscess, may follow appendicitis. In the latter, involvement commonly occurs by the portal vein; in the former the avenue is adhesions or lymphatic channels. It occurs only in the ascending type of appendicitis in which the pus gradually works its way up behind the cecum, colon and liver, finally forms a subphrenic abscess with abundant adhesions and encapsulations of the exudate all along this path. Finally perforation of the diaphragm occurs or the lymphatics carry the infection across into the thoracic cavity. The appearance of this complication is six to ten days after the onset of the appendicitis and usually during a period of remission in the symptoms of the primary lesion. With exceedingly rare exceptions it is on the right side, often confused with a hepatophrenic lesion, usually accompanied by active pain in the right hypochondriac region or right chest with fixation, nervous dry cough, and much dyspnea. Sometimes the pleurisy can not be outlined and shows only dry friction sounds, or the pus is deprived of much of its toxic effects, is practically sterile, or the effusion is purely serous and disappears promptly. Oftener the exudate is highly toxic, infective, putrid, gangrenous, very abundant with signs of a full chest, often followed by those of pneumothorax due to the evolution of gases by the gangrene. The prognosis, always serious, rests upon the general condition, the character and rate of the pulse, and the enfeeblement of the patient. In the presence of a right purulent putrid pleurisy a preceding appendicitis should be sought. Early surgical attack upon the pleurisy and the appendicitis is indicated. The patient, already highly toxic, usually dies; hence, the true treatment is prophylactic, in prompt diagnosis and relief of the appendicitis. In this way this and all other complications of appendicitis can be prevented.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscripts should be typewritten.

TETANUS AND ITS TREATMENT.

THE season of the year is again at hand when tetanus in our larger cities takes on somewhat the character of an epidemic. Last year some eighty deaths from the disease were reported in the Eastern States. It seems hopeless to expect any abatement of the yearly fireworks nuisance. Until this is attained the recurring danger from tetanus may be awaited with certainty. It is not the peculiarly-irritating quality of the burns made by the explosives, nor is it the contamination of the fireworks by the tetanus bacillus in packing that causes tetanus to result from these wounds. It is due to the fact that, in the seared and often lacerated wounds made by toy pistols, the tetanus bacillus, so common on our streets in the summer-time, finds beneath the surface of the skin, where it is well protected from all contact with oxygen, a favorable nidus for its anaerobic growth.

The prime indication for treatment is the free admission of air to every part of the wounded tissues. For this reason it is inadvisable to cauterize wounds in which there is fear of tetanus developing. The searing process, by the production of an eschar, effectually occludes the deeper tissues from the pervasive germicidal influence of the oxygen of the air. It is probable that the cauterization produced by the missile itself is an accessory etiologic factor in the original production of tetanus. For reasons similar to those which seem to contraindicate cauterization, strong antiseptics should not be used on a wound that is suspected of being infected with tetanus bacilli. In the spore-stage of the bacillus, which is the form in which it usually occurs in the presence of air, the tetanus bacillus is extremely resistent to the action of chemical germicides. It is futile, therefore, to attempt to destroy entirely the bacilli by such methods. The vital resistance of the tissues is sensibly lowered by their use and the dying tissue serves rather to protect the *bacillus tetanus* from the inhibitory influence of the free oxygen of the air.

The serotherapy of tetanus has not fulfilled its early promise, yet there still remain encouraging features in its use. When symptoms of severe tetanus have developed it is practically agreed that antitetanic serum is not of much service, at least when administered hypodermically. As a distinguished authority has said, the initial symptoms of tetanus, as we see them, do not herald the beginning of the disease, but really the beginning of death from the disease. If possible, treatment should anticipate the manifestation of the nervous symptoms of the disease. For this purpose the injection of antitetanic serum as a prophylactic seems advisable in cases in which there is good reason to fear that infection with tetanus bacilli may have taken place. Tetanus serum is now made of such high antitoxic value that the injection of two or three cc. of serum would be sufficient, in the presence of any suspicious wound, absolutely to guarantee immunity from the disease. The mortality of the disease is so high that prophylactic injection seems justified in all cases in which burns or lacerated wounds occur that have been contaminated by street dirt.

The intracerebral injection of antitetanic serum has not given all the good results that were expected from it. Those who have used this method of treatment most, however, speak very highly of it and will continue its practice in severe cases. Several cases successfully treated by the injection of antitoxic serum through a lumbar puncture have been reported. The serum so injected finds its way into the subarachnoid space and very probably also into the ventricles of the brain quite as effectually as if injected intra-

cerebrally. Moreover, a certain amount of the toxins of the disease that are known to exist in the cerebrospinal fluid are evacuated. This method of injection after lumbar puncture is far simpler than intracerebral injection. The latter is a major operation; the former can scarcely be dignified longer by the name of operation at all.

Cases of tetanus will unfortunately develop this summer as in other years. For these, early lumbar puncture with injection of 5 to 10 cc. of antitetanic serum should be tried. Where symptoms indicate a very severe type of the disease and of a fulminant character, a preliminary injection of a quantity of normal saline solution a little less than the amount of cerebrospinal fluid evacuated would serve to dilute the toxins of the disease and assist in their removal before they are fixed within the nerve-cells. This washing out of the spinal canal has been done a number of times, although not, we believe, in tetanus.

For suspicious street wounds, the prophylactic injection of tetanus antitoxin seems not only justified, but demanded as a duty by the present conditions of prophylactic therapeutics. Our bacteriologic knowledge of tetanus, its cause and its toxins, is a triumph of scientific medical advance. Unfortunately, all this knowledge has, as yet, brought but a modicum of benefit to clinical medicine. Let us hope, however, that our better realization of the conditions of the disease and the suggestions as to methods of treatment that are now before the profession will complete the successful practical application of the great scientific principles that have been established. The treatment of tetanus will be more fully amplified by Dr. Lambert in our next issue.

ECHOES AND NEWS.

NEW YORK.

Medical School Closed.—At a meeting of the corps of teachers of the New York School of Clinical Medicine, held at the Academy of Medicine, June 21, 1900, it was decided to wind up the affairs of the School and close it permanently. This action was taken in consequence of continuous interference of the lay Board of Trustees in its affairs.

St. John's Guild opened its Seaside Hospital at New Dorp, Staten Island, on June 15th for the reception and care of sick children and their mothers. Patients are being conveyed to the Hospital free of cost by the 10 A.M. and 2.30 P.M. Staten Island ferry, under the care of a nurse and orderly, until the Floating Hospitals are put into commission, which will be the early part of July. All patients are admitted free without regard to creed, color or nationality. Doctors may obtain tickets for distribution among their patients at the office of the Guild, No. 501 Fifth Avenue, upon application.

Contagious Diseases.—For the week ending June 23, 1900: Measles, 304 cases and 14 deaths; diphtheria, 257 cases and 30 deaths; laryngeal diphtheria (croup), 8 cases and 3 deaths; scarlet fever, 107 cases and 8 deaths; smallpox, 4 cases and 1 death; chicken-pox, 19 cases; tuberculosis, 178 cases and 135 deaths; typhoid fever, 18 cases and 9 deaths; cerebrospinal meningitis, 6 deaths; totals, 895 cases and 206 deaths.

To Cleanse Chinese Quarters.—The Board of Estimate has appropriated $20,000 for the Board of Health to use in fumigating the Chinese quarters in Manhattan, Brooklyn, and Coney Island. It is expected that when an attempt is made in Chinatown to carry out the work of fumigation, the scenes enacted in San Francisco will be repeated. The California Chinese appeared panic-stricken while the work was going on.

Broken Neck.—It is evident that all cases of fracture of the cervical vertebræ cannot expect the fortunate result that attended the recent successful case of Walter Duryea at Roosevelt Hospital. An operation was performed June 22 at Fordham Hospital upon a man who had fallen from a cherry-tree and sustained an injury almost identical with that of Duryea. The patient died a few minutes after recovering from the anesthetic.

Unreported Consumption Cases.—At a meeting of the New York City Health Board on June 25th, it was declared that there were 40,000 cases of consumption in this city during the past year, of which physicians reported but 9,000; the hospitals reported all such cases promptly, but "physicians were backward in reporting private cases." It is thought that a great many cases were kept secret in order to deceive life-insurance companies. Bright's diseases, it was declared, is ascribed to a great many cases in which tuberculosis is the primary cause. President Murphy directed that if physicians would furnish to the commissioners information to the effect that consumption exists in any given case, such information would be regarded as confidential.

Charges Preferred Against Dr. Jenkins.—Charges have been recently forwarded to Mayor Van Wyck against Dr. William T. Jenkins, Health Commissioner and brother-in-law of Richard Croker. The charges are sworn to by Dr. Willard P. Worster, of No. 203 West Eighty-first street, who has been engaged in practice in this city for the past thirty-six years. The charges allege: "That for the past three years the medical care of sailors has been diverted by William T. Jenkins, one of the Health Commissioners of the City of New York, from its legiti-

mate channels and so as to prevent healthy or honest competition.

"That, as your petitioner is informed and verily believes, the said William T. Jenkins caused to be incorporated a society in the city of New York for his benefit known as the Merchant Marine Hospital Service (Foreign) and Dispensary. That the business of said alleged hospital service and dispensary is alleged to be conducted at the Cheseborough Building, No. 17 State street, New York City. That said William T. Jenkins is the managing director; that one James Jenkins, his brother, is a clerk therein, but not a physician, who wears a badge marked, 'Health Department, City of New York,' and one J. S. Richardson is a doctor employed by said Jenkins and said society to visit ships and examine crews. That there is no hospital connected with the rooms or hospital service and no dispensary.

"That your petitioner is informed and believes that said business has been secured and is retained by said William T. Jenkins by representations made by him to ship-owners abroad and ship-owners' agents in this city; that he can and will favor their ships and crews by and through his office as Health Commissioner at this port."

PHILADELPHIA.

Public Baths.—The nine free public bathhouses were opened Monday, June 25th. Last year they were patronized by 3,500,000 bathers.

Chief of Charities.—Dr. John B. Shoemaker, lately appointed a member of the Board of Charities and Corrections, has been made president of that department.

Sterilized Milk and Ice Society.—This society has lately begun a new season's work. It supplies pure milk from tested herds at a very low rate and sterilized milk is retailed in one-cent bottles, this being sufficient for the feeding of one infant.

City's Work for Consumptives.—The eighth annual report of Rush Hospital shows the admission of 102 patients during the year. The Free Hospital has as yet no building, but has cared for 124 patients in other hospitals.

Health Report.—Deaths in the city for the week ending June 23d were 380, a decrease of 75 from the previous week and an increase of 1 over the corresponding week of last year. Contagious diseases: Diphtheria, 85 cases, 20 deaths; scarlet fever, 54 cases, 3 deaths; typhoid fever, 40 cases, 5 deaths.

Forests for Consumptives.—The State Forestry Commission is to purchase 40,000 acres of land at the headwaters of each of the three principal rivers of the State in order to rear forests. This is looking forward to the future State care of consumptives and also for outdoor recreation for other invalids.

CHICAGO.

Appointment of Dr. Nicholas Senn.—Dr. Senn has been appointed Chief of the Medical Staff of the Democratic National Convention, to be held in Kansas City July 4th.

Rush Faculty Dinner.—A dinner was given at the Chicago Club on the evening of June 30th by the Rush Medical College Facuty in honor of Dr. W. W. Keen of Philadephia, at which the majority of the members were present.

Rush Medical College Commencement.—Two hundred and eight medical students were given diplomas certifying that they are Doctors of Medicine by Rush Medical College, June 21st. The commencement exercises were held at the Studebaker Theater. The Doctorate Address was delivered by Dr. W. W. Keen of Philadelphia.

Mary Thompson Hospital.—This hospital is the defendant in a suit begun in the Circuit Court by Mrs. Anna Wolff, who seeks to recover damages in the sum of $5000. The plaintiff alleges that she was a patient at the institution two years ago, and that while there she had an operation performed from the ill-effects of which she has never recovered.

Chicago Medical Society.—The annual meeting was held June 20th. The Treasurer's Report showed 944 paid-up members. Hereafter the clinical meetings of the Society will be held alternately on the North, South, and West sides of the city. The Treasurer's Report showed a balance in the Treasury of $3,004.40. The following officers were elected for the ensuing year: President, Dr. James H. Stowell; first vice-president, Dr. Alexander Hugh Ferguson; second vice-president, Dr. Adolph Gehrmann; secretary, Dr. S. C. Plummer, Jr.; treasurer, Dr. Robert H. Harvey; trustees, Dr. William H. Wilder for the Ophthalmological Society; Dr. John Ridlon for the Orthopedic Society, and Dr. E. J. Doering for the Medico-Legal Society. Dr. Maurice H. Richardson of Boston delivered an address (by invitation) on "The Surgery of Gall-Stones." A vote of thanks was extended to Dr. Richardson for his interesting address.

GENERAL.

Red Cross Japanese Ship.—Japan has fitted up a hospital ship and sent her to Taku with arrangements to receive and treat the wounded of all the Powers.

Telephone Hygiene.—In Vienna telephone booths are furnished with napkins, bearing the inscription, "Wipe, if you please." The napkins are changed frequently, and this undoubtedly serves to keep the mouthpieces of the transmitters in good sanitary condition.

The Eclectic Medical Association.—This Association closed its thirtieth annual session at At-

lantic City June 21st. Chattanooga, Tenn., was selected as the next place of meeting. The following officers were elected for the ensuing year: President, E. Lee Stanley, St. Louis; recording secretary, Dr. Pitt Edwin Howes, Boston; corresponding secretary, Dr. N. A. Graves, Chicago; treasurer, Dr. W. T. Gemmill, Forrest, Ohio.

The Plague.—A fresh case of bubonic plague was reported June 23d at Oporto, Portugal. It will be recalled that a decree was issued February 7th last announcing that the bubonic plague had disappeared from Oporto, and that the quarantine of that port had been raised. No new cases have been discovered at San Francisco and it is generall believed that the stringent measures adopted have eradicated the disease. We know, however, as the *Journal of the American Medical Association*, says, that the plague often occurs sporadically before becoming epidemic—a fact that does not increase satisfaction with the present condition of affairs. It would be most unfortunate if, through misguided public sentiment or legal interference with quarantine, the pest should gain a foothold on the Pacific coast. Twenty-five new cases of bubonic plague were officially reported at Rio Janeiro, June 26th. There have been twelve deaths from the disease during the week.

Yellow Fever in Cuba.—The outbreak of yellow fever in localities hitherto exempt from the disease is ascribed to the recent heavy rains. Major Frank H. Edmunds of the First Infantry, who died at Quemados, Cuba, on Monday of yellow fever, at the age of fifty-one years, was stationed there as acting inspector-general on the staff of Gen. Lee, commanding the Department of Havana in Pinar del Rio. He was a graduate of West Point in the class of 1871, and was a native of Michigan, although appointed from Dakota. At Quemados two new cases are reported among the members of Gen. Lee's staff—Major Kean, Chief Surgeon, and Capt. Hepburn, Signal Officer. Capt. Hepburn's case is serious, but Major Kean's is light. Mrs. Edmunds, wife of the late Major Frank H. Edmunds, is convalescent. She has not yet been told of her husband's death. Havana has developed only three cases thus far, in spite of the gloomy predictions of what would occur as soon as the rainy season, from which the city did not suffer last year, was really at hand. The situation at Santa Clara City has materially improved since the troops were ordered out of the city limits. Gen. Lee's headquarters at Quemados will probably be moved to the camp in the neighborhood of Fort Columbia.

Investigation of Malaria.—It is stated in the *British Medical Journal* that next autumn with the cooperation of the Mediterranean, Adriatic, and Sicilian railway companies, experiments will be made on a large scale as to the prevention of malarial fever among railway servants in malarious districts in Italy. At all the stations which bear the worst name in regard to this scourge the huts in which the men and the families live will be protected with mosquito netting. Similar investigations will be pursued in Sicily and Sardinia. By this combination of research it is hoped to gain an accurate idea of the regional distribution and local characteristics of malaria in Italy, and to find means of prevention adapted to the condition of the different parts of the country. Dr. Koch, in the *Deutsche medicinische Wochenschrift* of Berlin, reporting from German New Guinea, under date of April 28, regarding his investigations respecting the origin and cure of malaria, says: "We have already established the fact beyond doubt that by prophylactic and subsequent treatment with quinine even the worst infected districts can be cleared of malarial infection."

Social Features of International Congress.—August 2d: An opening evening reception will be given in the name of the Government by the President of the Council.—August 3d: Evening reception by the President of the Congress.—August 5th: Evening reception to members of the Congress at the Palace of the Elysée by President Loubet.—August 8th: Evening reception by the Bureau and Committee of Arrangements at the Palace of the Senate and the Luxembourg Garden. A fête will be given by the Municipal Council of Paris, also several under the auspices of the various Sections.—The ladies accompanying members of the Congress will be invited to all of these and a committee of ladies has been organized to receive and entertain them.

Homeopathists Meet.—The fifty-sixth annual session of the American Institute of Homeopathy began its work at Washington on June 19th and ended on June 23d. The following officers were elected for the ensuing year: Dr. W. W. Van Baum of Philadelphia, president; Dr. A. B. Norton of New York, Dr. George Royal of Des Moines, and Dr. Flora N. Ward of San Francisco, vice-presidents; Dr. Eugene H. Porter of New York, general secretary; Dr. Wilson A. Smith of Chicago, recording secretary; Dr. T. Franklin Smith of New York, treasurer, and Dr. Henry C. Aldrich of Minneapolis, registrar. A resolution was adopted on June 22d declaring that a system of interstate comity was necessary to conserve the best interest of the medical profession and protect the community against imposition, and a committee was appointed to open communication with the National Medical Association and the Eclectic Society for the purpose of bringing about cooperation in an effort to secure such national or interstate legislation. The following was adopted as the definition of a homeopathic physician: "A homeopathic physician is one who adds to his general knowledge of medicine a special knowledge of homeopathic therapeutics and observes the law of similia. All that pertains to medicine is his, by tradition, by inheritance, and by right."A statue of Hahnemann, which has been erected on the East side

of Scott Circle in Washington was dedicated on June 21st.

CORRESPONDENCE.

OUR LONDON LETTER.

[From Our Special Correspondent.]

LONDON, June 21, 1900.

THE MARRIAGE OF FIRST COUSINS—ARMY SURGEONS AND THE VICTORIA CROSS—THE GENERAL MEDICAL COUNCIL—RAISING THE STANDARD OF PRELIMINARY EDUCATION FOR ADMISSION TO THE PROFESSION—THE POLYCLINIC DINNER—ANNUAL MEETING OF THE BRITISH DENTAL ASSOCIATION—ABSENCE OF PROVISION FOR THE CARE OF THE TEETH OF POOR CHILDREN—THE CENSUS—FRACTURE OF THE SKULL MISTAKEN FOR INTOXICATION.

IN the *Polyclinic*, the journal of the Medical Graduates' College, Mr. Jonathan Hutchinson has treated the interesting and practical question of marriage of first cousins in his usual lucid and able manner. He insists that idiot and deaf-and-dumb asylums are not disproportionately peopled by the offspring of consanguineous marriages, and that many isolated communities in which more or less close intermarriage has been practised for centuries are examples of all that could be wished in physical vigor. There is nothing in consanguineous marriage which necessarily leads to deterioration. But, of course, there is in the marriage of first cousins an increased probability that whatever tendencies exist in the family, good or bad, will be transmitted, since both parents possess them. Stock-breeders do not fear to bring together first cousins and from highly incestuous unions obtain the highest class of animals. In-and-in breeding long continued no doubt inperils fecundity and may even induce defective development; but it is only as regards single instances that the question arises in human affairs. The practitioner has not to say what would be the result if first cousins married in successive generations, but only in one. Advice is seldom asked regarding more remote relationship. As regards first cousins the reply should be "There is nothing likely to be prejudicial to offspring in a consanguineous marriage *per se*, but if there be any definite tendency to such diseases as tuberculosis, cancer, or insanity, there is a risk that it may be intensified. On the other hand, if the family has a good life-history there may be greater security in such a marriage than in one with a stranger whose antecedents are less known. However, some reservation must be made as regards certain rare maladies known as "family diseases." Of these retinitis pigmentosa is the most important. Liebreich and others have shown that it probably occurs with undue frequency in the offspring of consanguineous marriages. But in general the risks of in-breeding are simply the known risks of heredity and are in no essential relation with consanguinity.

The recent accession of Surgeon-Major Babtie's name to the list of Victoria Cross holders draws attention to the fact that only about twenty-one of these coveted decorations have been bestowed on living members of the medical staff. When it is remembered that surgeons are frequently in the danger zone and that they have none of the combatants blood-lust excitement and temporary madness, their cool courage should be all the more appreciated. The list includes Surgeon-Major Reynolds who took part in the heroic defence of Rorke's Drift; Surgeon Lieut.-Col. Hartley who rescued a corporal under a fierce fire, carried him to a place of safety, dressed his wounds, and then cooly returned to his ordinary duties; Surgeon-Major Hall who proved his courage on several occasions during the Crimean War and in one instance brought in several wounded men under a hail of bullets. Others are Surgeon-Major Crimmin who in the Burmese campaign in Eastern Heremi divided his attention between attending to the wounded and killing the enemy; Surgeon-Captain Whitchurch who during the sortie from the Chitral Fort in 1895 sought to bring a wounded captain to a place of safety and after three of the dhoolie bearers were killed himself carried the captain some distance.

At the meeting of the General Medical Council Sir John Batty Tuke, Chairman of the Education Committtee, presented a further report by that body on the question of raising the standard of preliminary examination in general education. It was thought impracticable to require all intending medical students to attain the standard of the so-called senior and higher grade examinations. A substantial advance on the present requirements could, however, be made by insisting on improvements on the character and stringency which could be directly influenced by the Council.

The annual dinner of the Medical Graduates' College and Polyclinic, held at the Trocadero Restaurant, was a most successful function. It was not altogether a festive affair, being partly given with the object of raising funds for the institution. Of these it is much in need, for, having no beds and not being a hospital in the ordinary sense, but simply a college for the instruction of qualified medical men where gratuitous consultations are held on suitable and selected cases, it does not appeal to the charitable public in the same manner as a hospital. Lord Strathcona and Mount Royal, who preseided, said that the object of the Polyclinic is to bring together medical graduates to their mutual advantage. Mr. Jonathan Hutchinson remarked that there is no competition between the College and the hospitals. Within the last twenty-five years there had been no increase in the number of beds in the hospitals while the population had increased immensely. The College, instead of being regarded as a rival, should be regarded with favor by the hospitals, for it affords some protection to them against the creation of new hospitals. He hoped that an arrangement may soon

be made by which students of the Polyclinic will receive instruction in the wards of the hospitals.

The annual meeting of the British Dental Association, which was held at Leeds, proved a great success. About 250 members attended. Mr. Brunton of Leeds, in his presidential address, pointed out that the dental departments of the hospitals fail to furnish all the aid required. Statistics showed that the school children of Leeds have 85 per cent. of their teeth decayed. In the Army and Navy no provision is made for the prevention or cure of dental disease. So much health and happiness depend on sound teeth that the subject ought surely to claim some little attention from the authorities and sympathy from the public. In the public charities of Leeds every part of the human economy except the teeth is cared for. No provision is made for any conservative dental work. Prof. Smithells of the Yorkshire College read a paper on "Flame;" Prof. Goodman on "The Strength of High Pressure Gas Cylinders;" Mr. T. S. Carter on "The Treatment of Fractured Maxilla by Wire Suture Aided by the Electromotor" and Mr. T. E. Constant on "Note upon a Misunderstood Movement of the Temperomandibular Joint."

Arrangements have already been made for the forthcoming census of Great Britain which will be taken in 1901. The first of the army of 50,000 men who will have the task of counting the population have been appointed. These are merely subordinate clerks. Before the time—a year hence—when the Registrar-General's Office will be hard at work arranging and compiling the schedules gathered from every inhabited spot of England and Wales, a vast amount of preliminary work must be done. For the purpose of the census Great Britain is divided into about 640 districts, each under a superintendent registrar. Each district will contain from 2 to 12 subdistricts approximately about 2000 in all and every subdistrict is again divided into enumeration districts numbering about 40,000.

That unfortunate error of diagnosis—mistaking a case of head injury for one of intoxication, seems to recur with remarkable periodicity. The victim was Captain Robinson, a nephew of Lord Rosmead. He was knocked down by an omnibus in the Strand and taken to Charing Cross Hospital, where he was supposed to be merely intoxicated. He was removed to the Bow Street Police Station. When in his cell, seven hours after the accident, the gaoler heard groans and heavy stertorous breathing. He found the prisoner lying face downward on the floor, unconscious and bleeding from the right ear. He was subsequently taken to Kings County Hospital, where he died eleven hours later from a compound fracture of the base of the skull. The coroner's jury censured the Charing Cross authorities for not making an adequate examination. Reports of similar cases occurring in the large cities of America are not uncommon and the mistake cannot be too strenuously deplored.

OUR PARIS LETTER.

[From Our Special Correspondent.]

Paris, June 18, 1900.

SPECIALTIES AT THE FACULTY OF MEDICINE—THE USE OF CACODYLE—RIVIERA RESORTS FOR CONSUMPTIVES—DEATH OF DR. APOSTOLI—TRANSPORTATION BY RAILWAY OF CASES OF INFECTIOUS DISEASES (GERMANY) — TYPHOID FEVER IN VIENNA—OVERCROWDING OF THE PROFESSION IN FRANCE.

It is a well-known fact that in the Paris Faculty of Medicine there is a lack of special instruction in such branches as otology, rhinology, laryngology, and disease of the eye. This was recently made the subject of an article by De Lavarenne, the editor of the *Presse Médicale*, in which he complains of the tardiness which is shown in following the example given by the German universities. For instance, Dr. Panas, the Professor of Ophthalmology, was about to take a vacation and no professor *agrégé* on the working staff could be found to replace him. The same condition prevails in the other specialties. A country physician, Dr. Filloux, has just left in his will a provision for a prize to be given to the interne and externe who pass every year the best examinations in otology, and this tends to show that there is a general awakening to the necessity of specialization.

Cacodyle, which has attracted so much attention of late in France as a cure for consumption, is still as much talked about as ever. Introduced by Dr. Armand Gautier, Professor of Chemistry at the Faculty of Medicine, this organic compound of arsenic has been tried by a large number of physicians in the hospitals. Administered by the mouth it seems to be attended with disagreeable eructations, a taste of garlic, and even general discomfort. Used hypodermically in doses of from five to ten centigrams daily, it is free from these results. Dr. Letulle, Professor *agrégé* at the Faculty of Medicine, has tried this preparation in his sanatorium. Over a thousand injections have been made in his service during the last four or five months, and no local irritation has been produced. They are made daily for a week, then stopped for a week. The following mode of preparation is recommended by Dr. Gautier:

℞ Cocodylate of soda, 6 grams, 40 centigrams;
Distilled water, 100 cubic centimeters:
Solution of phenic acid $^1/_{10}$ VI. drops.

This preparation should be boiled, filtered on a sterilized filter, and brought up to 100 cubic centimeters. Each cubic centimeter contains 5 centigrams. The results, according to Dr. Letulle, vary according to the condition of the patient. A great number of advanced cases, suffering from fever, and in a cachectic condition, are not much benefited; but certain forms with excavations, or with softening of the tubercles, are greatly improved. The appetite returns, the fever goes down, the weight increases. As to the blood-corpuscles, Dr. Letulle's investigations

are not as yet sufficiently conclusive.

At the recent Congress on Tuberculosis at Naples a question was discussed by Dr. Hérard de Besse of Beaulieu, which is of interest to American practitioners who intend to send patients to the Riviera. Dr. Hérard spoke rather *pro domo sua,* as he is practising at Beaulieu, and his speech tended to prove that this place was an ideal resort for consumptives, presenting a torpid form without much fever. The mean temperature in winter is 11° C., while that of Naples, Mentone or Cannes is 9° to 10° C., and the climate is tonic. What Dr. Hérard calls the "home-sanatorium" is in vogue at Beaulieu; that is to say, there are small private hotels, in which there may be from 15 to 20 guests and in which the life is much more quiet than in large establishments. Nice, as a place for consumptives, is quite out of the question, as it is exposed to the wind and dust, and the changes of temperature are often extreme. Cannes and Mentone are much better, and the latter offers the additional advantage of being less expensive.

Two weeks ago, in the last days of April, there died in Paris a man, who, without having any official title in France, with the exception of that of doctor, had acquired a world-wide reputation in electrotherapeutics. I am referring to Dr. Apostoli, whose name is well-known on account of his work in the medical treatment of fibromata. Dr. Apostoli's treatment has always been looked upon with disfavor by the greater number of surgeons and it is hardly likely that any man will be found to apply with as much *éclat* the treatment he had instituted for fibroids of the uterus. However, one already receives prospectuses from electrotherapeutists, who declare that their special knowledge of this field qualifies them to undertake such treatment. Of late years, however, Dr. Apostoli had employed static electricity as a means of toning up debilitated organisms, and his praises were sung by patients who had been subjected to his treatment. His success is an example of what follows ready adaptation to the popular idol of the hour of a scientific point of view.

A recent ministerial decision in Germany as to the conveyance of cases of infectious disease is of interest. All patients suffering from smallpox, diphtheria, scarlet fever, cholera, leprosy, must be transported in a special carriage upon payment of the tariff for this mode of transportation. Cases of measles, whooping-cough, or dysentery must hire a special compartment which is shut off from the rest of the train. The transportation of patients suffering from bubonic plague is forbidden. Suspicious cases will be treated according to the terms of the medical certificate. When a patient is suffering from an affection which makes him a source of discomfort to his fellow-passengers, he is obliged to take a special compartment. Such measures, as one can see, are drastic, but will certainly be useful.

Quite a scare has been caused in Vienna by the sudden increase in the number of deaths from typhoid fever. This city has been supposed to be a model one as to its water-supply, but typhoid fever has increased notably since the beginning of the year. From the 18th to the 21st of March there were 26 deaths, while there were only 25 from the 1st of January to the 3d of February. This is quite a difference, and an investigation is being held as to the cause of this sudden increase.

Last autumn Paris was also affected by a similar outbreak, but no cause for it could be demonstrated to the satisfaction of the people who were delegated for this undertaking, though it may be that some of the sources of the water-supply are not quite pure. It is generally in the latter part of summer that a certain amount of Seine water is distributed in the different arrondissements, and from the 1st of July it is prudent to boil the water or else take some of the mild mineral waters such as Evian, Anet, and Bussang.

During the last few weeks one has heard a great many complaints in France as to the increasing number of medical practitioners. Such a complaint would seem to be justified in other countries, but in France statistics show that the number of medical men has increased very little. In 1847 for a population of 35,500,000 inhabitants there were 17,375 doctors, whereas in 1876 there were 14,375 doctors for a population of 36,000,000 inhabitants. The number has increased slightly of late years, since in 1895 there were 15,017 doctors for a population of 38,517,976 inhabitants.

This increase is all at the expense of the cities, where the doctors have more and more a tendency to establish themselves, following out in this particular case the general laws. But it is easy to see how different this is from the proportion observed in England, where there are 35,000 medical men, or in the United States, where the number it seems is close upon 100,000. The French practitioner is, therefore, much better off than his confrère in England or the United States and he has less right to complain.

SOCIETY PROCEEDINGS.

AMERICAN MEDICAL ASSOCIATION.

Fifty-first Annual Meeting, Held at Atlantic City, N. J., June 5-8, 1900.

SECTION ON PRACTICE OF MEDICINE.

(Continued from page 934.)

THIRD DAY—JUNE 7TH.

Pathology of Rheumatism.—Dr. Riesmann of Philadelphia said that the nervous explanation of rheumatism, advanced originally by the elder J. K. Mitchell and adopted even by Charcot and later by Friedlander who placed the primary nervous lesion in the medulla, can no longer be thought at all probable. The diathesis theory,

especially that of the existence of an acidemia, is also improbable. Haig has recently called attention to this theory anew and put forward uric acid as the underlying cause. The presence of an increase of uric acid may, however, be an effect not a cause of rheumatism. As to lactic acid it seems to be proved that there is more lactic acid present in the blood of rheumatic patients. But this also may be an effect rather than a cause. The infectious origin of rheumatism is now admitted perfectly on all sides. The evidence for this origin is not direct nor *prima facie*. No specific micro-organism for the disease can be said to have been demonstrated as yet. This is, however, also true of syphilis, scarlet fever, chickenpox and smallpox, the infectious nature of which there is no doubt. It has been argued that the noncontagiousness of rheumatism and the fact that one attack does not protect against succeeding attacks are presumptive evidence that it is not infectious. Wagner of Leipsic, however, believes that he has noted the occurrence of contagion in rheumatism. It is possible that a short period of immunity from the disease occurs after an attack is over, but, as in diphtheria, this does not last long. The precedent chill which so frequently occurs and the occasional occurrence of hyperpyrexia point to the infectious nature of the disease. Rheumatism has been known to occur in epidemics. A number of house-epidemics have occurred, as in croupous pneumonia, that is, the disease has spread from person to person living in the same house.

Variations in Virulence.—Rheumatism varies very much in the number and severity of the cases which occur according to the season of the year. Carefully-collected statistics seem to show that it increases with the diminution of the rainfall and decreases when the precipitation is more abundant. This is opposed to the tradition which makes rheumatism occur especially in damp weather. The complications that occur in rheumatism, endocarditis, pericarditis, meningitis, venous thrombosis, are eminently characteristic of an infectious disease. The port of entry of the infectious material has been pointed out. Heberden first suggested that the throat was the portal of invasion. Angina has been noted in about 70 per cent. of all rheumatism cases. Otitis media has certainly been the primary focus of infection in a certain number of cases. Attacks of rheumatism have been noted to occur immediately after operations on the nose, after vaccination and after operations for fistula. It is probable also that in a certain number of cases the intestine is the port of entry. Cases of rheumatism are not pyemia, or, if so, they are very mild. The endocarditis certainly seems to proceed from a bacterial agency. It has been noted in two cases that pregnant women suffering from rheumatism have given birth to children suffering from the disease.

Kind of Bacteria.—Maclagen says that the causative agent for rheumatism is probably a miasm, that is, an agent like that which produces malaria. The analogy between rheumatism and malaria is not, however, very striking. The joint-fluid of rheumatism is as a rule sterile. Where micro-organisms have been demonstrated in it, it is hard to get away from the idea that they were due to accidental contamination. Singer made a series of examinations of the urine of patients suffering from rheumatism, and finding a number of different kinds of micro-organisms concluded that it was a modified pyemia. Chvostek repeated Singer's observation, but did not confirm his results. It is probable that polyarthritis rheumatica has not a single cause, but is due to a series of micro-organisms.

Rheumatism as an Infection.—Dr. J. J. Walsh of New York said that fifteen years ago Eichhorst in his "Handbook of Practical Medicine" transferred rheumatism from among the constitutional diseases to the class of infectious diseases. At the Charité Hospital in Berlin rheumatism finds a place in Professor Koch's department, that of infectious diseases. In the other pavilions around it are tuberculosis, scarlet fever, measles, leprosy and smallpox. The sentiment that the disease is an infectious one has been growing for a long time. Rheumatism has all the hall-marks of an infection. The prodromal symptoms, the fever, the fact that it is a self-limited disease, as was first pointed out by Austin Flint, the occurrence of complications all over the body and of hyperpyrexia, all point to an infectious disease. In autopsies made on patients who died during the acute stage cloudy swelling of the heart and of the liver and kidneys and enlargement of the spleen have been found. No definite bacterial cause can be said to have been demonstrated with certainty as yet. A form of diplococcus, has, however, been found in Germany by several observers and also by French investigators. It is probable that the ordinary form of the disease is due to this diplococcus. Anomalous cases are due to other micro-organisms and to secondary infections. Some of the rapidly fatal cases are probably due to the anaerobic bacillus which was isolated by Achalme from several fatal cases.

Treatment of Rheumatism.—For a long time the alkali treatment enjoyed a great reputation. The introduction of the salicylate has, however, pushed the alkali treatment into the background. It is the custom to say that the salicylates shorten the course of the disease, besides relieving the pain and the fever, and that they prevent to a certain extent at least the occurrence of heart-complications. Careful statistics collected at the city hospital in Berlin, in which, during alternate periods, salicylic acid and so-called indifferent treatment, that is, by means of iodides and so forth, were employed, show that this claim is not substantiated. The pain and fever are relieved somewhat sooner. The course of the disease, however, is not shortened. The heart-complications are a little more frequent and the stay in the hospital a little longer under salicylate treatment than under different treatment. The

salicylates only act as an antipyretic analgesic. Any of the other coal-tar products are just as efficient. Leyden in Berlin now uses antipyrin instead of the salicylates. Gerhardt uses phenacetin. These relieve the pain and the fever and it is claimed lessen the tendency to heart-complications. As a matter of fact, it is doubtful if the antipyretics have really not done harm in the end. They have given relief to the patient and so have enabled him to get up much sooner than he would under other methods of treatment. The only thing of any importance in rheumatism is the heart-complications. The mortality from the disease is practically nil—less than one-tenth of one per cent. For the avoidance of heart-complications, and especially to make their effect as trifling as possible, rest is absolutely necessary. Even in the healthy the heart beats ten times more per minute in the standing than in the reclining position. When fever is present it beats 20 or 30 times more per minute. This extra work at a moment when a poison that is especially liable to act upon the heart is present is the occasion for the development of severe heart-complications.

Rheumatic Endocarditis of the Essence of Rheumatism.—Although called such, rheumatic endocarditis is not a complication but just as essential a part of the disease as the joint-affections. The endocardial process begins on the edges of the valves where they come in contact. The endoarthritic process begins at the points of contact in the joints. We can not hope, as a rule, to prevent the spread of rheumatism from one joint to another. Neither can we keep it from affecting in most cases the joints, so to speak, of the heart. So-called heart-complications occur in from 50 to 75 per cent. of all cases of rheumatism. In patients under fifteen years of age the heart is affected in from 80 to 90 per cent. of the cases. Not infrequently the endocarditis is the only lesion of rheumatism present. It runs its course without affecting any of the joints, but is just as truly rheumatism as if all the joints were affected. The one hope in rheumatism is to lessen the work of the heart, not only during the acute course of the disease, but more particularly afterward when the inflammatory exudate on the valves is in a plastic condition, and may be reabsorbed under the influence of the iodides. The treatment for rheumatism, then, is not the antipyretics, the salicylates, antipyrin, etc., except in as far as these are necessary to relieve symptoms. The iodides and rest with proper diet are the most hopeful remedies we have.

Chorea and Rheumatism.—Dr. Charles W. Burr of Philadelphia said that in chorea there is frequently a history of precedent rheumatic fever, especially a story of pain, rheumatic in character. It is well known too, that children who have St. Vitus' dance are more liable later in life to attacks of rheumatism. At autopsies made on children suffering from chorea the one lesion that is found in practically all the cases is valvular heart-disease. In nearly all of the cases collected by Dr. Osler this was true. Dr. Burr, himself, has seen the autopsies of three cases in which valvular endocarditis was present. Rheumatic sore throat not infrequently precedes the development of St. Vitus' dance. The connection, then, between these two diseases seems clear. Yet clinically it is hard to reconcile the manifestations of St. Vitus' dance with rheumatism. As we see them, the patients are often strong, well-built children, who have suffered from a fright or some severe emotion, or who from overwork or overstudy (especially overdevotion to piano practice in young girls), develop the choreic movements which characterize the disease. This certainly does not look like an acute infection and has no similarity with acute rheumatism. The connection between the two diseases has become a tradition in medicine, however. Recent French observers have claimed the discovery of a microbe in the blood of patients suffering from St. Vitus' dance which when injected into animals produced choreic movements. The observations are, however, too few to justify any conclusions in the matter, and as St. Vitus' dance looks entirely unlike an acute infection the question remains an open one. Further study will be well repaid if it shows us the reason for the coincidence of the two diseases.

Heart in Rheumatism.—Dr. Delancey Rochester of Buffalo said that heart-affections occur after rheumatism in 60 per cent. of the cases. The younger the patient the greater the liability to heart-trouble. Sir William Watson saw only two cases of rheumatism in children before puberty that did not develop endocarditis. Endocarditis is as essential to the disease as are the joint-affections. More common even than endocarditis is myocarditis. Some affection of the heart-muscle occurs very early in the disease. The heart-murmur in rheumatism is often due to myocarditis. It can be observed before the time when any mechanical interference with the valves from endocarditis could have occurred. A corresponding murmur is heard in anemic cases. Pericarditis is not so common, but occurs in nearly ten per cent. of the cases and should always be looked for. Murmurs heard at the base of the heart in rheumatism are nearly always due to pericarditis. They may also be heard in the third or fourth interspace along the sternum and may be taken for tricuspid murmurs. Certain observers have noted a separation of the left clavicle from the first rib, because of the bulging pericardium. One of the striking features of rheumatic pericarditis is the frequent development of nervous symptoms. The interference with the blood-supply to the brain is responsible for them. They may be so severe as to arouse a suspicion of meningitis. When delirium occurs in rheumatism, look for pericaditis. Not infrequently the presence of a pulsus paradoxus will call attention to the existence of a pericarditis. The usual physical signs will be found on examination of the chest.

Arthritis Deformans.—Dr. A. O. J. Kelly of Philadelphia said that the name arthritis defor-

mans is less objectionable than rheumatoid arthritis, for the disease has nothing to do with rheumatism, or than rheumatic gout, for the disease is far from being a hybrid combination of rheumatism and gout. The features of interest in the disease is its pathogenesis. There are not only joint-lesions in the disease but pathologic conditions of the muscles and the vasomotor system. The disease is not due to anemia, nor is it due to uterine reflexes, or to wear and tear of the system, for, although these have been set down as causes, they are not sufficient to explain the origin of the disease. Two theories for its etiology seem worth considering, *viz.*, the neural and the bacterial. Neither one of these is sufficient of itself fully to account for the disease and both are probably concerned in its etiology. There is no doubt that emotion, fatigue, fright, and such conditions, have a causal relation to the disease. It also occurs during the menopause and after frequent pregnancies and prolonged lactation. These point to its neurotic origin. Garrod has collected five hundred cases of the disease and only 89 of them in men. It is evident, then, that the nervous element must be given a place in the ultimate pathogenesis of the disease. Vasomotor and the trophic changes are very noticeable. Ataxic joints represent a very similar condition. The disease has been called a trophoneurosis. Peripheral neuritis has been found in some cases and spinal changes have been noted in a few instances. These substantiate the nervous theory and yet leave the cause of the disease obscure since they do not occur in all cases. In tabes, lateral sclerosis and syringomyelia nervous lesions are invariably present. The reflex action of the uterus in the disease is at least doubtful since the uterus is under the domination of the sympathetic system rather than of the cerebrospinal axis.

Bacteria in the Disease.—A number of bacteria have been found in the disease. Their causative relation is in doubt. The results of inoculation are very indefinite. Chiffard and Raymond describe what they call a slender diplococcus which was found in the disease. This was found not only in the joints, but also in the glands in the neighborhood of affected joints. It is well known that arthritis deformans occurs as a sequel of other infectious diseases. The bacterial influence in the disease seems undoubted. The disease is not a pure trophoneurosis, but an infectious trophoneurosis. It is not a peripheral neuritis, since changes in the peripheral nerves are not constant. The spread of the disease is usually centripetal, but this does not point necessarily to the nervous origin of the disease and, besides, its progress is sometimes irregular and not centripetal. The muscular atrophy that is noted in the disease resembles somewhat that due to joint-lesions, but not entirely. It is not as gradual as atrophy from joint-disuse. There is a mixed cause, a toxic element in conjunction with the nervous basis. The affection of the muscles resembles that caused by the neuritis set up by such toxins as diphtheria or by alcohol. The analogy is certainly sufficient to put beyond all doubt the existence of a bacterial element in the etiology of the disease.

Rheumatism an Infection.—In discussing the papers on rheumatism Dr. Frederick Packard of Philadelphia said that one of the evils of modern medicine is snap diagnosis, words taking the place of ideas. It is easy to say "rheumatism" where pain exists and lo! a diagnosis is made. One of the greatest clinicians in the country is accustomed to say after careful examination of a patient, "Now this is chest; this is abdomen," and will not say more until he has studied the case very seriously. In the old days the word dropsy occupied a place corresponding to rheumatism in our day. It was a convenient word, but expressed absolutely no definite idea. We talk of rheumatic angina, of rheumatic endocarditis, of rheumatic pleuritis, terms that serve only to mask for us the true condition. Like scarlatinal and gonorrheal rheumatism they should be expunged. There seems no doubt now that acute arthritis is an affection due to a specific microorganismal cause. Secondary infections there are and infections that resemble ordinary acute arthritis. When we have said this, however, a number of problems remain to be studied. Why, for instance, are chorea and endocarditis so intimately associated with rheumatism? Why do eczema and rheumatism sometimes seem to be connected? It is clear that more lactic acid is present in the blood during rheumatism than at other times. This seems, however, to be an effect not a cause. Benjamin Ward Richardson's experiments, by which he demonstrated that the injection of lactic acid into animals produces heart-complications and arthritis, are not enough in themselves to demonstrate that lactic acid is the important causal element in rheumatism. The infection in rheumatism usually takes place from the throat.

Dr. Musser said that rheumatism now seems beyond all doubt to be an infection. It is not a single disease, however, but a combination of many types of disease which we are as yet unable to distinguish. It remains for the clinician to point out the differential diagnosis of the various forms of the disease, for this will materially aid in the exact treatment of the condition. The field is a most precious one for ambitious investigators.

Dr. J. M. Anders of Philadelphia said that chorea seems to occur especially in those of the rheumatic disposition. Rheumatism certainly often follows in later life. The endocarditis that is noted so often in chorea is an effect and not a cause of the disease. The murmur that is noted is sometimes functional. Just as the muscles of the limbs refuse to act properly, so the muscles of the heart do not act as usual and murmurs result. At times fever is noted in chorea and then it will not infrequently be found that acute endocarditis may exist as a complication of the disease. This should be looked for carefully, as its

bad effects can to a great extent be avoided by proper treatment.

Osteomyelitis and Rheumatism.—Osteomyelitis is sometimes mistaken for rheumatism. Dr. Anders has recently seen two cases. Osteomyelitis, however, never occurs in a joint, but in a long bone, although it may be in the vicinity of a joint. With care the joint can be moved without producing pain, while this cannot be done if the case is rheumatism. Besides, osteomyelitis occurs, as a rule, in but one place while rheumatism is usually polyarticular. It must be borne in mind, however, that in certain cases of subacute osteomyelitis and these are the ones that are liable to be confounded with rheumatism the foci of suppuration may be multiple.

Dr. Charles G. Stockton of Buffalo said that heredity undoubtedly plays a rôle in the causation of arthritis deformans. It seems old-fashioned to talk about the arthritic diathesis, but in this disease, at least, a truth is expressed by the term that might otherwise be lost sight of. It is probably in the nerves that the heredity basis of the disease is situated. It must not be forgotten that meteorological conditions affect joints. There are old people who are able to foretell the changes in the weather. It is probable that the changes in joints which cause this discomfort are also predisposing conditions for rheumatism.

Dr. Bishop of New York said that, although the infectious nature of rheumatism is becoming more and more clear, we cannot get away entirely from the idea that the cause of the disease is some defect in the chemistry of the body. Rheumatism is certainly a nutritional as well as an infectious disease. Acute articular rheumatism is a specific infectious disease, the predisposition to which is acquired by disturbances of metabolism.

Dr. H. D. Favil of Chicago said that we must wipe off the slate and begin anew our studies of the etiology of rheumatism. The infectious element now seems certain. The diathetic element is losing some of its old potency in the disease, but cannot be neglected entirely.

Dr. Birnie of Maryland said that an important element in rheumatism on which sufficient stress is not usually laid is that it is a self-limited disease. It is probably true, as Dr. Walsh said, that no drug serves to shorten the course of the disease. Rest in bed and careful diet are the important remedies for lessening the number and severity of heart-complications. The iodides, potassium iodide and ferric iodide, used after the acute stage, are very beneficial drugs. The symptoms pains and fever must be relieved, but their relief must not be followed by allowing the patient to be up and around before convalescence is fully established.

Rheumatism Precedes Chorea.—Dr. J. J. Walsh said in closing the discussion that chorea is a nervous disease. Its motor symptoms are due to irritation of the cells of the cortex. This irritation is due to disturbances of the blood-supply. The disturbances of the blood-supply are consequent upon chronic endocarditis. The one lesion that is constantly found at autopsies in cases of chorea is chronic valvular disturbance from endocarditis. After a fright, or a severe emotion, or after overstudy or overwork, this disturbance of the circulation becomes manifest. The chronic endocarditis is due to a precedent attack of rheumatism which ran its course either in infancy and was completely ignored, or a little later in life and was set down as growing pains, or was insidious, as a rheumatic endocarditis without joint-lesions. It is the occurrence of the earlier attack of rheumatism that makes these children liable to rheumatism later in life. Chorea follows, however, not only rheumatism but any infectious disease which affects the heart. Of late years particularly it has been known, although more rarely than rheumatism, to follow measles and scarlet fever and even mumps and chicken-pox.

Dr. Delancey Rochester said that rest is extremely important in rheumatism. The occurrence of endocarditis does not contraindicate the use of the salicylates. Saline cathartics should be used freely and the patient should be wrapped in blankets rather than sheets, and should be made as comfortable as possible for his six to eight weeks of rest in bed.

Malignant Endocarditis.—Dr. N. S. Davis, Jr., of Chicago reported a case in which frequent chills and fever had occurred without any cause being traceable except malignant endocarditis. The patient ultimately recovered. It seems probable that in this case the site of primary infection was in the digestive tract. The patient had suffered for a long time from chronic gastritis. In another case under Dr. Davis' care the primary seat of infection seemed to be a chronic enteritis. Dr. Davis thinks that we cannot draw any hard and fast lines between simple and malignant endocarditis.

Muscular and Valvular Heart-Lesions.—Dr. S. Solis-Cohen of Philadelphia said that in most cases the site and nature of the valve-lesion in heart-disease is much less important than the state of the cardiac muscle. The most important exception to this rule is mitral stenosis with extreme narrowing. Aconite is often a useful drug to reduce the excessive muscular effort in this condition and its employment must not be neglected. In some cases in which none or but very slight valve changes can be demonstrated, there may develop signs of severe cardiac insufficiency due to lesions of the myocardium. The physical signs of myocarditis are inconstant. Where there are no valve-lesions intermittence or irregularity of the pulse and precordial pain in non-neurotic subjects are the symptoms that call attention to the myocarditis. Tinitus, vertigo, dyspnea, visceral congestion and edema may be slight and escape notice. Usually the first sound of the heart is weak and distant and the two sounds become more nearly alike, the second sound being accentuated. Later embryocardia and galop-rhythm may develop. Gout, syphilis, alcohol and

tobacco, tea and coffee, sexual excesses, mental strain and physical overwork are the chief causes of disease of the myocardium, apart from lesions that are due to acute infections or are secondary to nephritis or valvular disease. Influenza is a frequent cause of myocarditis.

Diagnosis of Myocarditis.—We have not sufficient clinical knowledge as yet of the disease to permit of its assured recognition antemortem. The differential diagnosis between neurasthenia of the heart and disease of the myocardium may be extremely difficult. It is important to avoid error, for the prognosis and treatment of valvular disease depend mainly on the proper estimation of the condition of the heart-muscles. Failure to recognize the presence of myocarditis may be very serious if a heart should be judged to be normal because of the absence of murmurs and the patient be advised accordingly. If the presence of myocarditis is recognized the treatment consists of judicious regulation of the diet and exercise, the avoidance of the exciting causes mentioned and of excesses of every kind, with the regulation of the habits of life, so as to secure a good functional condition of the skin and other eliminative organs. Warm saline or carbonated baths and in most cases gentle massage, with resistance exercise carefully adapted to the individual cases, are of great benefit. Nitroglycerin is the most useful single agent of the materia medica. Strychnine, digitalis cactus, strophantus and spartein are useful in special cases. Arsenic, gold and sodium chloride and iron are the most suitable tonics. Potassium iodide and mercurials have special indication in many cases. Venesection should be done promptly and in sufficient amount if sudden and urgent symptoms of cardiac failure develop.

Clinical Myocarditis.—Dr. Bishop of New York said that myocarditis is much more frequent than has been thought. Its recognition is extremely important because on it depends the prognosis of many cases. The myocardium and its affections are even more important than the pericardium and the diseases to which they are liable. The most important causes of myocarditis are rheumatism, syphilis, gout, alcoholism and the other intoxications, and arterial diseases. Arteriosclerosis is an especially important etiological element in the production of myocarditis. Dr. Bishop then discussed a series of cases of myocarditis in which the irregularity of the cardiac rhythm was the most striking symptom of the heart-affection. In the treatment of these cases he has found the Schott method of carbonated baths, with resisted movements, especially useful.

Rational Prognosis in Heart Affections.—Dr. J. J. Morrissey of New York said that in making the prognosis of heart-affections it is important not only to estimate the nature and extent of the changes which have occurred in the heart itself, but also the condition of other important organs of the body far removed from the thoracic cavity, but dependent on the proper continuance of the circulation for their perfect functioning. The history of cases is extremely important because it enables us to judge of the progressive character of the affection and how rapidly degenerative changes take place in the heart itself and in the organism. The mere finding of a heart-murmur is not sufficient to justify a gloomy prognosis. The condition of the cardiac muscle, the length of time the lesion has existed, and the presence of dilatation, or hypertrophy, or both, are important factors in modifying our prognosis. The occupation and temperament of the patient are very essential elements to be considered for making our prognosis. The diagnosis should be complete, the prognosis tentative. As Professor Allbut says, "Give your prognosis on the best suppositions; treat your patient on the worst."

Murmurs and Prognosis.—Murmurs do not invariably mean endocarditis. The prognosis based simply on a murmur is utterly unjustifiable. It has been well said that, with an apex beat in the normal situation and regular in rhythm, the auscultatory phenomena may be practicalyl disregarded. It must not be forgotten, especially, that a presystolic murmur does not always indicate the most serious of all lesions, namely, a mitral stenosis. A so-called musical apex murmur has no special significance in prognosis, as it indicates nothing more than the passage of a stream of blood through a small aperture in the segment of the valve. As regards longevity, aortic stenosis is a favorable lesion and Dr. Morrissey differs from the authors who state that it appears for the most part after middle life. It is often found during that period when a man should be at the highest point of physical capacity—between thirty and forty. It is frequently present, it is true, as a part of general decay, as a consequence of atheromatous changes in the vascular system. But it is more frequently present than has been hitherto suspected, without necessarily involving such pathological manifestations. It is important not to alarm a young man by the diagnosis heart-disease, because some hypertrophy of the heart is discovered. These athletic hearts may occur in the midst of perfect health and yet life be embittered by the suspicion of heart-disease aroused by the injudiciousness of an attending physician. Patients should be told to return for further examination when the mind cannot be thoroughly made up as to what condition is present. An interval of a very short time may cause the disappearance of apparently significant symptoms. There are more snap diagnoses of heart-disease than of any other condition, and more of them are wrong.

Statistics of Heart-Disease.—Dr. Morrissey has had under his care 255 cases of cardiac disease. Of these 69 suffered from aortic disease, 18 were cases of pure aortic insufficiency, six of aortic stenosis, and 45 of aortic insufficiency and stenosis; 185 suffered from mitral lesions, 95 from mitral insufficiency, 74 from mitral insufficiency and stenosis and 14 from mitral stenosis. In only two cases did there seem to be fatty degeneration

of the cardiac muscle. Dr. Morrissey is of the opinion that fatty degeneration of the heart is diagnosed much more frequently than there is any justification for in the physical signs or the rational symptoms presented by patients.

Endocarditis and Myocarditis.—In the discussion of heart-diseases Dr. Frank Billings of Chicago said that ulcerative endocarditis is much more frequent than has been thought. When intermittent fever occurs and no malaria can be demonstrated, or remittent fever and typhoid fever and tuberculosis can be excluded, it is always probable that ulcerative endocarditis is present. Myocarditis is also more frequent than has been thought. Its foundations lie in faults of nutrition in the gouty and other diathesis, in imperfect digestion and absorption, and its first symptoms are often an irritability of disposition, the symptoms of indigestion, a lessened amount of urine, an enlarged liver and other symptoms which point to disturbances of the capillary circulation.

Dr. Herrick of Chicago said that for the prognosis of heart-disease the condition of the heart-muscle is more important than the determination of the exact site of the valvular defect. He saw not long ago an old man of sixty-nine who had been told by Skoda of Vienna thirty-seven years before his death that he had heart-disease. By careful living he succeeded in living on absolutely without cardiac symptoms almost to his seventieth year.

Dr. Fussell said that certain symptoms are given too great significance in heart-disease. An increase in the area of heart-dulness, for instance, is only significant if persistent and if compensation fails. An easily-recognizable condition which will often raise suspicion of heart-disease is the existence of a fringe of dilated veins along the costal margins.

Occupation and Tuberculosis.—Dr. Freudenthal of New York read a paper on this subject, which will appear later in the MEDICAL NEWS.

Prebacillary Stage of Consumption.—Dr. J. M. Anders of Philadelphia said that the most important thing in the treatment of pulmonary tuberculosis is an early assured diagnosis. It is possible to recognize the disease with reasonable certainty before tubercle bacilli are demonstrated in the sputum. The Roentgen rays are an important aid to this prebacillary diagnosis. The shadow of beginning consolidation at the apex of a lung is distinctly darker than the surrounding tissue long before the presence of the lesion can be demonstrated by percussion or auscultation. The diaphragm on the side on which the lesion exists can also be seen to make shorter excursions than on the healthy side. The tuberculin test, used with proper precautions, can also be of the greatest service for early diagnosis. A reaction to tuberculin will make an assured diagnosis long before the physical signs are sufficient to justify more than a vague suspicion. The careful history of the case will often lead to a very probable diagnosis of tuberculosis when the physical signs are insufficient to raise more than a suspicion. Antiphthisical treatment is often indicated before tubercle bacilli can be demonstrated in the sputum. It must be remembered that tubercle bacilli may often remain encapsulated in the pulmonary tissue, or at least shut off from any connection with the bronchi, until the disease has made extensive inroads. The modern treatment of consumption can only do good in any case, and, if the patient has been losing weight and a suspicion of tuberculosis exists, the open-air treatment of the disease should be instituted until the patient recovers the weight lost. If tuberculosis were treated always in the preliminary stage, there is comparatively little danger of death from the disease. Suspicion, then, if well grounded, should be enough to cause the physician to insist on the change of life necessary to institute proper hygienic measures.

Rest in Tuberculosis.—Dr. Carroll E. Edson of Denver, Colorado, insisted on the importance of rest in pulmonary consumption. His paper will appear in full in the MEDICAL NEWS.

Serotherapy of Tuberculosis.—Dr. C. P. Ambler of Asheville, N. C., presented the report of 106 cases of pulmonary tuberculosis in all stages treated by antituberculous serum. After a year and a half of observation he is now able to confirm the report read before the Section on the Practice of Medicine at Columbus last year. This year's experience confirms the conclusion that tuberculous patients treated with serum do not relapse as do those treated with creosote and other allied drugs. Cases of tuberculosis recognized early in the course of the disease can be absolutely cured and practically assured against relapse by this treatment. The symptoms of patients in advanced stages of the disease can be relieved better by this method than by any other. The comfort of the patient is especially assured and the course of the disease is rendered slower than by any other treatment.

Nitrogen Injections for Pulmonary Tuberculosis.—Dr. A. F. Lemke of Chicago read a paper on tuberculosis of the lungs treated by compression with nitrogen after the method of Murphy, with some remarks on the *rationale* of the procedure and a record of experiments upon dogs. Dr. Lemke said that compression for pulmonary tuberculosis is suggested by clinical evidence. Stokes says, "In many cases where pulmonary tuberculosis complicated by pneumothorax becomes chronic, we may observe a singular suspension of the usual symptoms of phthisis. The sweats cease, the pulse becomes quiet, the patient may gain flesh and strength to a surprising degree." Jaccoud, Williams, Cornet, Osler, Fowler, Godlee and Paget give confirmatory cases. Pathological evidence in favor of this view is found in the writings of Hughes, Rokitansky, Watson, Späth, Rosenbach and others. Laennec once said, "No consumptive succumbs to a first attack of consumption." Tuberculous lesions always heal by cicatrization. The rational proceeding is to further the natural tendency to cic-

atrization. The danger from tuberculosis lies in the dissemination of the disease throughout the lungs or the body. The paths of dissemination are first, by continuity and contiguity and, secondly, throught the air-channels, the lymph-vessels and the blood-vessels. Compression favors fibrosis in and about tuberculous areas. It occludes the avenues of dissemination of the virus and by compressing cavities puts them in a favorable mechanical condition for healing. Indirect favorable effects of the compression are, first, rest to the lung as a whole; second, the evacuation of secretions by the pressure exerted; third, the prevention or diminution of absorption of toxic substances; fourth, the prevention of secondary infection, and, fifth, the diminished tendency to hemorrhage.

Observed Effects of Compression.—There is good evidence that it furthers the natural tendency on the part of the tissues to cicatrize. Clinically it is an excellent palliative remedy, for it diminishes cough, expectoration and sweating, lowers fever and causes an almost immediate tendency to gain in weight. There is not any evidence that fresh tubercles can develop in a compressed lung. There is now good clinical and experimental evidence that healthy lung-tissue may be compressed for a year or more and yet retain its capacity for expansion upon the removal of the pressure. Experiments upon dogs were detailed in which the left pleural cavity was injected with nitrogen or normal salt solution every two weeks during a period of eight months. The changes that took place were of not a character to determine permanent effects upon the lung-tissue.

Technic of Nitrogen Injection.—The nitrogen is injected through an ordinary exploring needle inserted in the anterior axillary line, at its intersection with the mammillary line. The average quantity of nitrogen which may be introduced into the pleural cavity without untoward effect is 120 cubic inches. The actual risks of the operation of intrapleural injections of nitrogen are extremely small. Accidents have not been reported since the first report was made. Subcutaneous emphysema has not occurred in any case since the adoption of the intercostal splint.

Uses of Intrapleural Injection.—These may be summed up as follows: (1) They are curative in pulmonary tuberculosis in its incipient stages. (2) They are palliative in cases in which the disease is too extensive to hope for recovery and give a prolonged life for weeks or months in comparative comfort. Besides, they greatly diminish fever and expectoration. (3) One of the most useful purposes of these injections is to check pulmonary hemorrhage; cases have been reported in which intrapleural pressure at once stopped the hemorrhage after all ordinary measures had failed. (4) They compress cavities and so establish mechanical conditions that will permit healing. (5) They serve a useful purpose in compressing the lung just prior to operation in which the pleural cavity is to be freely opened, and they can be used to determine the presence or absence of pleural adhesions, before opening the pleural cavity in order to drain abscesses or bronchiectatic cavities, cysts, etc. These cases in which it has been useful to surgeons are most interesting.

Silver Injections Over Vagi Nerves.—Dr. Thomas J. Mays of Philadelphia made a further report on his method of treating consumption by the injection of silver nitrate along the course of the vagi in the neck. The counterirritation produced stimulates the vagi and, as these nerves carry trophic influences to the lung, the lung conditions are modified, the resistive vitality is increased and the tuberculous process is gradually overcome. The injections are made by lifting up the skin over the vagi and throwing in a quarter of a grain of nitrate of silver. As the injection is painful, a preliminary syringeful of weak cocaine solution should be used. Even before the injections are made, the nerve will sometimes be found to be tender along its course on the affected side. Dr. Mays has now used this method in over a hundred cases and he has obtained with it better results than with any other.

In the discussion Dr. Vaughan of Ann Arbor said that the development of tuberculosis in patients suffering from argyria is not unusual. The use of nitrate of silver, then, does not seem very promising.

Dr. Delancey Rochester said that tuberculosis is often disseminated through tailors. The thread is frequently passed through the mouth and the hands are not kept clean while handling the clothing. Thus, the seeds of the disease are carried into families where it did not exist before. Exercise, he said, is bad for consumptives, not only because of the exhaustion it produces, but also because the deep inspirations necessitated by exertion lead to the carrying of particles of tuberculous material into other and as yet unaffected portions of the lungs.

Dr. S. Solis-Cohen said that a very important aid in the diagnosis of incipient tuberculosis is the daily temperature. Usually it is highest from twelve to two. An inverse temperature-course, that is, with the highest point in the morning, is always suspicious of tuberculosis.

Dr. S. Knopf of New York said that the two secrets in the treatment of consumption are not to treat the disease, but the patient, and, secondly, not to consider that any particular climate is specific, but that the open air will cure any incipient case of tuberculosis. Besides tailors, there are two other classes of workmen who are especially liable to tuberculosis. They are the helpers in laundries who sort the soiled linen and workmen engaged in sorting rags. With regard to the rest-cure in tuberculosis, there is one danger that must be borne in mind, *viz.*, the development of hypostatic congestion if patients are kept continually in one position. Massage is an important remedy in tuberculosis, giving, as it does, exercise without fatigue. Creosote is not followed by any special tendency to relapse. Landouzy controls

cough by the injection of sterilized water, just under the clavicle. Cough is best controlled by discipline.

FOURTH DAY—JUNE 8TH.

Diagnosis of Diabetes.—Dr. James B. Herrick of Chicago said the diagnosis of diabetes ultimately depends in all cases upon the detection of sugar in the urine. As the urine of all patients cannot be examined, it is important to recognize the symptoms that point to the existence of sugar in the urine and so awaken the doctor's suspicion. A number of nervous symptoms occur very early in the disease. Sexual impotence is often the first sign of the existence of diabetes. Although Naunyn thought differently, psychic illusions are quite common in Dr. Herrick's experience. Irritability and a change of disposition are often the first sign. There are three causes why diabetes is missed by the practitioner, *viz.*: (1) The urine is not examined; (2) sugar is not present, or (3) it is present only intermittently. Other features of the disease may overshadow the fundamental affection. Albuminous urine and the occurrence of casts may lead to the diagnosis nephritis when the true condition is really diabetes. Casts are sometimes a warning of the approach of diabetic coma. Sugar may occur even in urine of low specific gravity. This is true (*a*) if patients are very weak; (*b*) if interstitial nephritis is present, and (*c*) if large quantities of liquid have been taken shortly before the examination is made. The urine of every case of pulmonary tuberculosis and of obscure coma should be examined carefully. For purposes of treatment and prognosis the character of the diabetes should be recognized. The diet of diabetics should never be too strict, otherwise serious complications may be precipitated. The presence of obesity usually adds to the favorableness of the prognosis. The condition of the pancreas and the liver should be made out as far as possible in order to give more certainty to the prognosis.

Increase of Diabetes in New York.—Dr. Heinrich Stern of New York discussed the mortality from diabetes mellitus in New York since 1894. During these six years there have been 1867 deaths from the disease. Of these 931 almost exactly half have been in women. Before this the disease was considered to be from two to two and a half times as frequent in men as in women. The present statistics are probably an indication that, in the struggle for existence, woman is no longer exempt from the strenuous life. While the total death-rate in New York has declined from 25 per 1000 to about 18 per 1000, the death-rate from diabetes has increased from $2^1/_2$ per cent. in 1894 to over 5 per cent. in 1899. The number of deaths are approximately the same throughout the different parts of the year. Five per cent. of the deaths occurred in persons over 45 years of age. The occurrence of nervous manifestations about the time of the menopause makes the death-rate from diabetes in women very high during the years between forty-four to forty-eight. In the cases under twenty the number was equally distributed between males and females, which seems to show that the same conditions of life prevail for both sexes at this time. During eleven years in New York only fifteen deaths from diabetes were reported in the colored race. This means, perhaps, no more than that the disease fails of diagnosis among these people, who are notoriously known to be satisfied with a home-made diagnosis and many of whom are afraid of hospitals. The increase in the death-rate from diabetes in general does not, perhaps, mean more than a better recognition of the disease than previously.

Skin Symptoms of Diabetes.—Dr. Milton D. Hartzell of Philadelphia said that certain cutaneous symptoms are so commonly associated with diabetes that they had been called by Fournier diabetic skin-diseases. Pruritus is the most common of these. It occurs especially about the genitalia and down the thighs and may give rise to the most intense itching. Scratching may lead to the development of eczema. There is nothing peculiar about the pruritus and eczema except their location. Preputial inflammation is very common during diabetes and may lead to thickening of the foreskin and the occurrence of fissures. Balanoposthitis occurs as a consequence of retention of urine behind the foreskin and the fact that the sugary urine forms such an excellent culture medium for the micro-organisms. Pustular acne is a very common condition in advanced diabetes. Crops of furuncles and of carbuncles are frequent. It is estimated that more than one-third of the cases of furunculosis and multiple carbuncle are due to diabetes. Papillomatosis diabetica has been noted in at least one case as a fungating, capillary mass on the back of the hand. Moist or dry gangrene of the skin is a not infrequent complication of diabetes. It may occur in a single or in multiple patches. At times it is symmetrical and may be mistaken for Reynaud's disease. It can be differentiated from this, however, by the absence of the preliminary disturbances of the vasomotor mechanism which are so characteristic of Reynaud's disease. Kaposi has reported certain cases of bullous gangrene which began as dark-colored vesicles and then spread. Xanthoma diabetica deserves the name because it occurs nearly always in connection with glycosuria. It consists of patches of red flat papules on the knees, elbows and buttocks. Dermatitis herpetiformis has been noted occasionally in connection with diabetes. The deposit of pigment in the skin in certain cases of the disease has given rise to the term bronze diabetes. This type of diabetes has been studied especially by French authorities. The treatment of the skin-complications of diabetes should be preventive. It consists in the most scrupulous cleanliness. Eczema and other skin-diseases will frequently resist all local treatment unless the diabetic condition is improved by proper treatment, hygienic and dietetic.

Early Diagnosis.—Dr. S. Solis-Cohen in the discussion said it should be borne in mind that glycosuria is not diabetes. Glycosuria may be noticed particularly after certain of the infectious fevers. After influenza it is not infrequent. Patients must not be disturbed by the announcement of the existence of diabetes until the physician has assured himself that the condition is persistent. It is important to remember that albuminuria may coexist with glycosuria and the finding of albumin in the urine should not keep the physician from looking for sugar. The only way to avoid missing cases of diabetes is to examine the urine of every patient even although the complaint be nothing more than an ingrowing toe-nail. This is evidently not feasible. Hence, the suspicious symptoms should be borne in mind. The nervous symptoms should especially call attention to the urine; and of these bilateral sciatica is one of the most characteristic.

Increase of Diabetes.—Dr. J. J. Walsh of New York called attention to the fact that according to the mortality statistics diabetes is very much more frequent in this country than it was ten years ago. Insurance companies are now refusing three risks for diabetes to one refused ten years ago. Dr. Stern has pointed out that diabetes in New York is nearly three times as frequent as it was only six years ago, although the general mortality of the city has decreased by one-fourth during the same period. This increase of diabetes is probably apparent and not real and is due to the fact that the disease is more often recognized than it used to be. Two fatal diseases especially are mistaken for diabetes—pulmonary consumption and chronic nephritis. The sugar in the blood of diabetics makes it an excellent culture medium for the tubercle bacillus. Practically all the slow-running cases of diabetes die of pulmonary tuberculosis. To permit a diabetic patient to associate with those affected with tuberculosis is almost inevitably fatal. When diabetics become affected with tuberculosis the loss in weight and other symptoms of the diabetes are attributed to their tuberculosis and the underlying disease remains unrecognized. Almost the same thing happens with regard to nephritis. Some irritability of disposition is perhaps the first symptom that calls attention to the condition of their urine. An examination is made, albumin is found and casts, both these abnormal constituents being frequently present in diabetic urine; sugar is not looked for and the case is considered to be simply one of advanced nephritis.

Dr. Morrissey of New York called attention to the fact that glycosuria frequently exists in tuberculosis. In a hundred cases carefully examined for this purpose, he found at least traces of sugar in the urine of over 30 per cent.

Dr. Roussel of New York called attention to the fact that sugar may occur in the urine in cases of myxedema. In an undeveloped case of myxedema recently under his care the patient was treated for a long while for diabetes, but without marked improvement. The sugar disappeared as soon as thyroid was administered and the symptoms of myxedema were gotten under control. The sugar remained absent as long as the thyroid treatment was kept up, but returned when the patient after a year, under the impression that her cure was complete, stopped thyroid medication for a time. In these incomplete cases of myxedema both sugar and albumin occur in the urine and they may be mistaken for either diabetes or nephritis.

Dr. Osborne of New Haven said that in only about fifty per cent. of the cases of diabetes is there found on postmortem a lesion of the pancreas. The remaining 50 per cent. are due to lesions of other organs than the pancreas. A number of patients who have Graves' disease suffer from glycosuria. Most of the patients with severe Graves' disease die either of diabetes or tuberculosis. Acromegaly is often complicated by diabetes. In all of these obscure conditions of glands having internal secretions, careful examinations of the urine should be made in order to detect the presence of sugar. In pancreatic diabetes regulation of the diet does good. In diabetes from other causes even a strict diet has not much effect.

Distribution of Diabetes.—Dr. Herrick of Chicago said that it is computed from statistics in Berlin that there is more diabetes in the upper 10,000 than in the lower 100,000. Perhaps this infrequency of diabetes among the poor accounts for its rare occurrence among the negroes in this country. Dr. Herrick has seen diabetes in a negro but once. Obesity makes the prognosis of diabetes much better. What has been called diabetogenous obesity readily yields to dietetic treatment. The vigorous enforcement of an absolutely proteid diet is sure to do harm rather than good, besides inflicting a great deal of discomfort on the patient.

THERAPEUTIC HINTS.

Treatment of Hemorrhoids in Women.—For hemorrhoids when they are flabby and indolent, or dry and warty, no treatment is instituted. If they are swollen when examined, the pain can be mitigated and the suffering and itching relieved by rest, a frugal diet, saline purgatives and cold injections, which lessen the constipation. When there is a discharge apply, with the patient in bed, compresses of bran and water, or of a solution of zinc sulphate, of glycerin and tannic acid, or perhaps some ointment of calomel. If the external swellings are inflamed, stay in bed and apply compresses of cold water or an ice-bag. When they discharge and ulcerate and restrict the passage of matters, and the sitting position or walking is painful, the thermocautery heated to a cherry-red gives relief. But care must be taken not to burn all the projections of the anal region for fear lest a slower contraction result. Finally, combat the constipation by the use of ovules of glycerin.—Lutaud (*Bul. gen. de Therapeutique*, March 8, 1900).
